Radial Velocities of Stars, Nebulæ and Clusters.—Vol. 18 of the Lick Observatory Publications consists of a useful catalogue of radial velocities compiled by Joseph Haines Moore. All the results obtained at the Lick Observatory and at its southern station in Chile are included, also those at eighteen other observatories, systematic corrections being applied to all classes of observations for which their determination is possible. The results of the separate observatories are given for each star, also an adopted value with its estimated probable error. The stellar portion of the catalogue occupies 199 pages with an average of about thirty stars on each. Then follows a short catalogue of velocities of 133 gaseous nebulæ; these are all galactic objects except 18 in the Magellanic Clouds. Another list includes the results for 18 globular clusters, mainly obtained by V. M. Slipher at the Lowell Observatory. Finally there are radial velocities for ninety extra-galactic nebulæ, mainly obtained at the Lowell Observatory and at Mount Wilson. The spectral shift is expressed as radial velocity, but with a note that this is only done for uniformity with the rest of the catalogue, not asserting that this is its true interpretation. The velocities are nearly all positive; there are the well known exceptions of the Andromeda nebula and its two companions, also M. 33 and N.G.C. 6822. The largest recessional velocity is 19,700 km./sec. for a nebula in Leo, R.A. (1900) $10^h22{\cdot}0^m$ N.Decl. 10° 56′.

The Structure of Cellulose and Related Substances

THE discussion arranged by Section B (Chemistry) of the British Association on September 2, on the constitution of polysaccharides with special reference to fibres, was perhaps a happy example of what such discussions should be and disarms some of the criticism which has recently been levelled against the programmes of certain of the sections. The results of recent researches in this difficult but fascinating field were presented for the most part in a lucid manner which rendered them intelligible to scientific workers generally and not merely to specialists in this particular field. For this some credit must undoubtedly be given to the formal arrangement of the discussion; the gap left by Prof. M. Bergman, who was unable to be present, was well filled by Prof. L. Zechmeister.

Prof. W. N. Haworth opened the discussion with a survey of the development of our knowledge of the constitution of polysaccharides in which the fundamental contribution of the work of the Birmingham school in establishing the structure of the mono- and di-saccharides was emphasised. The structure of cellulose, for example, rests ultimately on the constitution assigned to the disaccharide cellobiose, and the mutual linking of β-glucopyranose residues in a chain through positions 1 and 4 of the glucose molecules is the fundamental principle of the modern cellulose structure. Recent work by Haworth and Machemer has indicated that information on the approximate length of the chains and as to whether they are open or closed can be obtained by a study of the fully methylated derivative of cellulose, obtained by methylation under very mild conditions in which no important degradation or decomposition of the macro-molecules occurs. Since if the macro-molecule is in the form of an endless chain, each glucose unit ultimately yields 2 : 3 : 6-trimethylglucose, while if the chain terminates one of the terminal groups yields a molecule of tetramethylglucose, and a quantitative separation of the tri- and tetramethylglucose is possible, the hydrolysis method can be used to determine the structure of the chain. The formation of 0·6 per cent of tetramethylglucose accordingly indicates a mean average length of about 100–200 glucose units for the terminated chains in cellulose. The average molecular weight of 30,000 thus indicated is in good agreement with values obtained from X-ray data and by the use of Svedberg's ultra-centrifuge method. Values obtained by this method for the chain length of a long series of cellodextrins are in excellent agreement with those obtained by viscosity measurements or by determination of the iodine value.

Prof. H. Staudinger then described the viscosity method of investigating the nature and size of the colloid particles of cellulose and related substances. An exhaustive study of synthetic polymeric substances of known constitution parallel with that of the 'polymer homologous' series of degradation products of cellulose showed that in sufficiently dilute solution the relation between their molecular length and viscosity in solution is expressed by the viscosity law:

$$\eta/c = K_m . M$$

where η is the specific viscosity, c, the concentration, K_m a characteristic constant for each polymer homologous series and M the molecular weight. In these solutions as in solutions of cellulose in Schweizer's reagent or of cellulose acetate or nitrate in organic media the colloid particles are the molecules themselves and do not have a micellar structure. The 'polymer homologous' series of degradation products of cellulose obey the same law and these methods lead by extrapolation to a molecular weight of 120,000 for cellulose in Schweizer's reagent, 750 glucose residues being combined in one molecule. The molecules are long threads which in one dimension are 500 times longer than in the other two. Viscosity relations also afford evidence of the presence of a 6-carbon atom ring in the glucose residues of cellulose.

Prof. L. Zechmeister's paper discussed the unexpected behaviour towards enzymes of polysaccharides of comparatively small chain-length (4–8 glucose units). Dr. Zechmeister suggested that in enzyme reactions the length of chain of the reacting molecule as well as the character of the groupings present is important. The field of investigation thus outlined is of the greater interest in view of Mr. W. T. Astbury's suggestion of the existence of a fundamental relation between protein chains and polysaccharide chains.

Dr. E. L. Hirst then discussed the question of the molecular structure of starch and its allied products glycogen and inulin. In starch the mutually linked glucose residues are united by α-glucosidic linkings in contrast with the β-glucosidic linkings of cellulose, while the α-linkings of starch do not readily give a straight chain pattern but favour the formation of interlocked aggregates of the macro-molecules, which in presence of water are hydrated with formation of micellar solutions. Recent work has shown that the differences between amylose and amylopectin do not depend on the phosphorus content. On careful acetylation and methylation the special characteristics of each modification are retained and since the purified and fractionated methylated derivatives both yielded 5 per cent of tetramethylglucose, the macro-molecules of amylose and amylopectin both consist of terminated chains of 24–30 glucose units (mean average mol. wt. 4000–5000) and the differences between amylose and amylopectin depend on hydration and interlocking of the macro-molecules and on micellar structure. Glycogen is built up on a plan similar to that of starch and differs from amylose in having a macro-molecule containing only 12–14 glucose residues in the chain. Similarly inulin has been found to consist of a terminated chain of about 30 fructofuranose residues mutually linked through positions 1 and 2, the macro-molecule probably terminating at one end in a reducing group. The corresponding molecular weight (about 5000) is in good agreement with estimates made by direct methods.

Prof. H. Mark gave a critical review of the bases upon which the accepted formula for cellulose rests, and showed how a combination of the chemical methods which had established the structure of cellobiose and the disaccharides, the application of X-ray methods, and the researches of Prof. Staudinger on the nature and size of molecules of colloidal substances had led to a picture of the cellulose molecule and of the arrangement of molecules in the fibre which in many respects may be considered as definitely established. From a detailed examination of X-ray data including data recently obtained by the

application of new methods Dr. Mark described the arrangement of the glucose units in the fibre and of groups of these chains associated as micellar bundles, the length of the chain being about 100–200 glucose residues, in agreement with the value obtained by the chemical methods of the Birmingham school.

The final paper by Mr. W. T. Astbury described the application of X-ray methods in the field of protein chemistry, where again the combination of the results of organic chemistry and physical methods has established the concept of long chain molecules. Protein fibres are built up of polypeptide chains in various states of extension whereas cellulose appears to be laid down in biological structures as fully extended chains. X-ray methods have as yet revealed only two proteins, the fibroin of natural silk and the β-keratin of stretched hair which are in a fully extended state. Since in natural processes the formation of cellulose and other polysaccharides seems to be effected through the intervention of proteins, it is possible that the protein chains may act as a pattern or framework upon which the sugar units are laid down as a preliminary step to their linking together in polysaccharide chains. It is an interesting point that the chief longitudinal spacings of muscle and of unstretched hair are almost equal to the length of a glucose residue as it occurs in cellulose and the fact that the crossed-cellulose chains of the wall of *Valonia ventricosa* are laid down according to a definite plan indicates that they have been built on a net-work pattern in the underlying protoplasmic layer.

Sixth International Congress of Genetics

NOTWITHSTANDING the small number of European delegates attending, the International Congress of Genetics held at Cornell University, Ithaca, New York, on August 24–31, was a marked success. This was mainly owing to the large amount of preparatory work undertaken by the Organisation Committee, the Executive Council and the Local Committee. Although many papers were not read in the absence of their authors, the programme was still overcrowded, and the volume of proceedings containing the abstracts of papers and descriptions of exhibits runs to more than four hundred pages. The exhibits alone would have furnished ample material for a busy week. Numerous laboratories in several buildings were devoted to exhibits, in which cytological demonstrations played a prominent part; but they included also living and dried specimens illustrating genetic experiments with fungi, liverworts, mosses, ferns, numerous cereals, economic and other plants, as well as collections of varieties of maize and vegetables and numerous floricultural exhibits. The animal exhibits included *Drosophilia* and *Sciara*, Lepidoptera, Orthoptera, bees, aphids, *Gammarus*, tunicates, echinoderms, molluscs, fishes, rats and mice, foxes, pigeons, guinea-pigs, and all the domestic animals, many of the latter as living specimens.

FIG. 1.—Genetic garden at the Sixth International Congress of Genetics, Ithaca

A unique feature of the Congress was the genetic garden (Fig. 1), contributed to by geneticists who had sent seeds from many parts of the world. Here were demonstrated and compared side by side the various forms, hybrids and mutations, of *Zea*, *Œnothera*, *Nicotiana*, *Primula*, *Antirrhinum*, *Pharbitis*, *Helianthus*, *Pisum*, etc. A special feature arranged by Prof. Emerson was the display of the numerous mutations of *Zea* in their proper order in the ten chromosomes, as determined by linkage investigations. A chart also showed the loci of more than eighty genes in maize.

The cytological demonstrations were so many that, although a hundred microscopes must have been in use, each exhibit could only be set up for one afternoon. The work on maize chromosomes by the Cornell group was the basis of excited discussions. The great detail of chromosome structure and behaviour observable in maize is in marked contrast to *Drosophila*, although here, too, numerous cases of visible translocations were demonstrated.

The morning sessions were devoted to general papers grouped under such topics as the nature and cause of mutations, the interrelations of cytology and genetics, the genetics of species hybrids and the contributions of genetics to the theory of organic evolution. On the afternoons of the last three days the Congress divided into six sections for the reading of a very large number of more specialised papers. The grouping of these was under such topics as general genetics, cytology, animal genetics, human genetics, methods and technique, and genetics and pathology. Numerous papers were concerned with *Drosophila* and a number bore on chromosome structure, especially in relation to crossing-over.

The presidential address by Prof. T. H. Morgan was on "The Rise of Genetics".

The evenings were taken up with informal group conferences on such subjects as the nature of the gene, poultry linkage work, mice, maize, size valuation, fish genetics and human genetics. Motion picture films were shown of the developing fowl blastoderm, living cells in mitosis and sexual reproduction in *Mucor*.

On the last day of this crowded week the Congress met at the New York Agricultural Experiment Station, Geneva, where the papers, exhibits and demonstrations related mainly to fruit and vegetable breeding and agricultural bacteriology. This was followed by excursions to New England and Canada, while others dispersed to see the solar eclipse of August 31.

The Congress must have been a great stimulus to everyone who took part in it, for it served to show that genetics is still a rapidly expanding field, with innumerable practical applications in plant and animal production and also with a widening basis in relation to general biological theory. Many papers showed how technical is becoming the investigation of the *Drosophila* mutations and the production of mutations in many organisms by X-rays. Perhaps the most general advance indicated since the last Congress in 1927 is the increasing intimacy of relationship demonstrated between chromosome structure and genetic behaviour.

The British delegates included Prof. Ruggles Gates and Prof. F. A. E. Crew, representing the Government, and Dr. R. A. Fisher, Prof. J. B. S. Haldane, Dr. C. C. Hurst, Dr. C. D. Darlington, Dr. Honor Fell and Dr. John Hammond.

Progress of Aeronautical Research*

THE Aeronautical Research Committee's report of the year's work reflects the general slowing up of all progress consequent upon the reduction of expenditure, in that there has been little new research undertaken, but a good deal of cleaning-up of outstanding detail has been accomplished.

New experimental apparatus has received a good deal of attention. At the National Physical Laboratory the new compressed air tunnel is in working order, and an early obsolete tunnel is being rebuilt with an elliptical cross section and a much higher speed. The R.A.E. has the new vertical free flight tunnel in operation. A modification giving an increase of speed in the new open jet tunnel, and a new high-speed water tank are both practically finished. A 24 ft. full scale tunnel is in hand, and should be working by the end of 1933.

The work on spinning has been collected and collated, and design rules for ease of recovery from, or for complete avoidance of, spinning, have been developed. An interesting sideline in these experiments has been the development of wing-tip parachutes, which can be released at will to act as brakes on the spinning machine. It is suggested that these will reduce the danger when carrying out spinning tests on new type machines, the properties of which in this respect have to be found by actual experiment.

Further research on 'buffeting'—an effect first brought into prominence by the failure of a German D.V.L. aircraft over Meopham—suggests a remedy which in cases appears to clash with that needed to cure spinning. Buffeting can be minimised by keeping the tail plane "in the lowest practicable position in relation to the wings", while for the avoidance of spinning it is necessary to raise the tail plane with respect to the fin and rudder. These contradictory requirements appear to indicate a disadvantage of the low-wing monoplane which has not previously been realised.

The problems of stability and control are adequately met by the development of various forms of slots and interceptors, and as a result of the intensive investigations upon these questions the report suggests that there is now sufficient information in existence to enable designers to achieve a sufficient degree of safety by "correctly shaping and arranging the wings and tail organs without using additional mechanisms on the wings". Similar remarks are made with regard to wing or tail flutter. Airscrew flutter is unfortunately not so completely understood, and further investigations into this are proposed.

Interference between various adjacent parts of an aeroplane has now been dealt with up to the stage at which it is possible to isolate the various causes and deal with them separately.

A new term, "spoiling drag", has been introduced to indicate an additional drag due to the rotary motion of the airscrew slip stream upon the bodies in it. Suggestions for counteracting it with radial vanes are offered, as the result of wind tunnel experiments.

Attention is directed to the very rapid increase of size of sea-going aircraft during the last few years and to the necessity of keeping pace with this in research, as many new problems due to increase of size are arising. For example, the change of hydrodynamic pressures on hull bottoms during take-off and alighting are giving rise to problems upon the elasticity of the material of the hull plating.

The effect of accelerations imposed upon the aircraft by gusts is now being taken up. Vertical gusts with velocities up to 30 ft. per second have been recorded under the edges of certain types of clouds, and there is reason to suppose that even larger ones may be found in stronger winds. Statistical recording accelerometers are being developed for use on aircraft operating over established air routes. On the theoretical side the effect of accelerations on the aerodynamical characteristics of the various parts of a machine is being investigated.

The position with regard to research on aero-engines is peculiar in that it appears that there is little scope for further radical improvement in the present weight of 1·5 lb./H.P. with a fuel consumption of 0·5 lb./B.H.P./H.P. Any further reductions could only be made at the expense of reliability and length of life, but attention to details, such as cooling methods, that allow the engine and aeroplane as a whole to have a better streamline form, will possibly result in an improved performance being obtained for the same power and weight of engine. It is suggested that there is a greater probability of reducing this drag by, say, 20 per cent, than of cutting down either weight or fuel consumption by a similar amount.

In theory, fuel economy is being hindered by unsatisfactory induction pipe distribution in multi-cylinder engines, and the absence of a control of fuel-air mixture production which automatically adjusts itself to changing air conditions. Direct injection of fuel into the cylinders would remove both of these weaknesses.

Work on compression-ignition engines is progressing both with engines and fuel. It has been decided that the two-stroke direct spray type holds

* The Aeronautical Research Committee Report for the Year 1931-32. H.M. Stationery Office, 2s. net.

out the best possibilities of success for aircraft work, and a new experimental unit is being built. Fuel oil has been found to respond to various doping mixtures, and a small addition of ethyl nitrate renders inferior oil superior to the highest grade when undoped.

The report appreciates the fact that there has been a considerable increase in the amount of research work done at the universities. Direct aeronautical research is now being carried out at Bristol, Cambridge, Glasgow, Imperial College (South Kensington), Manchester and Oxford.

University and Educational Intelligence

CAMBRIDGE.—Mr. N. Dean of Trinity Hall has been appointed University lecturer in estate management.

The Appointments Committee of the Faculty of Biology 'B' gives notice that it will shortly proceed to appoint a University lecturer and a University demonstrator in biochemistry. The duties will commence on January 1, 1933. Particulars as to stipend and duties may be obtained from Sir Frederick Gowland Hopkins, at the School of Biochemistry, to whom applications should be sent on or before November 9.

The degree of M.A. has been conferred on Prof. R. S. Hutton, of Clare College, Goldsmiths' professor of metallurgy.

In accordance with its usual practice, Trinity College announces the offer of a research studentship open to graduates of other universities who propose to go to Cambridge in October next as candidates for the degree of Ph.D. The value of the studentship may be as much as £300 a year if the pecuniary circumstances of the successful candidate require so large a sum. The College also offers, as usual, dominion and colonial exhibitions to students of dominion and colonial universities who wish to go to Cambridge next October as candidates for the degree of B.A., M.Litt., M.Sc., or Ph.D. These exhibitions are of the titular value of £40, but their actual value is such sum (if any) not exceeding the titular value as the College Council may from time to time hold to be justified by the exhibitioner's financial circumstances. If it is made clear that the financial need of an exhibitioner cannot possibly be met by the payment to him of the full amount of his titular emolument, the Council has power, if funds are available, to award him an additional payment. Candidates for the research studentship and the exhibitions must apply through the principal authority of their university, and applications should reach the Senior Tutor (from whom further particulars may be obtained) by July 1, 1933.

WALES.—At a meeting of the Court of Governors of the University College of Wales, Aberystwyth, held on October 19, it was reported that Sir Julien Cahn has promised to provide a sum of £3,000 a year for a period of seven years. This money will be utilised for large-scale experiments on the improvement of poor soils at the Welsh Plant Breeding Station. Principal Stuart-Jones has accepted the invitation of the Council to retain the principalship for another year. Prof. G. A. Schott, professor of mathematics, has been appointed vice-principal of the College.

OXFORD.—On October 18 a decree was passed by Congregation constituting a Committee for Ornithology with the duty of establishing and supervising an Institute of Ornithology. The functions of the Institute, the formation of which was foreshadowed by Dr. F. Homes Dudden, the previous Vice-Chancellor, in his valedictory address, will be to carry out research into problems of ornithology, with special reference to the numbers, distribution, movements, habits and economic status of British birds; to collect, co-ordinate and supply information on these subjects obtained from published sources and from field observers, and to publish the results of its work by means of printed papers, informal instruction, or lectures. The Institute will be independent of any single University department but will work in co-operation especially with the Departments of Zoology and Comparative Anatomy and of Rural Economy. The decree creating the Institute does not come into force until May 1, 1933, and it is one of the functions of the new Committee to select the staff.

THE Council of the Institution of Naval Architects has made the following awards: Parsons scholarship in marine engineering (1932), to Mr. Allan M. Baxter, of Messrs. G. and J. Weir, Cathcart, Glasgow; Denny scholarship in naval architecture to Mr. John R. White, of Macclesfield Grammar School, and the Denny scholarship in marine engineering to Mr. K. F. Leonard, of the Ealing County School, London; Duke of Northumberland prize (in connexion with the 1932 examinations for National Higher Certificates in naval architecture) to Mr. Norman Holey, of the Technical College, Sunderland.

THE superintendence of the work of rural school teachers in the United States of America forms the subject of two recent bulletins, Nos. 6 and 7 of 1932, of the Office of Education. These supplement the studies, recently noticed in these columns (see NATURE of Oct. 15, p. 589), of the present status of the rural school teachers themselves, and afford further evidence of the keen interest now taken in rural education in that country. In "The County Superintendent in the United States" by the professor of rural education, Cornell University, attention is directed to the magnitude and the difficulty of the work of this functionary. While recent improvements in means of communication must have facilitated the inspection of schools in sparsely populated tracts, the task which falls to the lot of the typical superintendent with 145 teachers in 55 schools under his jurisdiction is a formidable one. In addition to supervision he has to attend to problems of finance, buildings and their equipment, pupil classification and progress, curricula, consolidation and transportation, etc. The intrinsic difficulty of these problems is aggravated by the fact that he has to deal with many local boards. Only a minority have a supervisory assistant and only about half have clerical help. In more than half the States the superintendent is elected by popular vote and in these 43 per cent are women and the median salary is 1848 dollars. In the other States, where appointments are made by county boards or State officials, the percentage of women superintendents is 5-18 and the median salary ranges between 2259 and 2773 dollars. An improvement in the salary situation is necessary, we are told, in all the States if the rural schools are to attract and hold professional men and women of ability.

Calendar of Geographical Exploration

Nov. 2, 1841.—Afghanistan and Its Borders

Sir Alexander Burnes was assassinated while acting as political agent in Kabul. Burnes became an interpreter in Surat when only seventeen years of age and developed a keen interest in the history and geography of north-western India and the adjacent countries. In 1832, disguised as an Afghan, he started from Lahore, made his way across Afghanistan to Balkh, thence to Bukhara, Astrabad and Teheran, and across Persia to Bushire. In 1835 he returned to Afghanistan, taking with him John Wood. The latter explored the Kabul River, crossed the Hindu Kush mountains to the Oxus, and explored that river to one of its sources. He gathered much information about the nomad tribes of that region.

Nov. 3, 1924.—The Rio Negro and its Tributaries

Dr. Hamilton Rice made his first air survey in the 1924–25 expedition to the Rio Branco and Uraricoera. Rice's valuable work on the northern portion of the Amazon basin began in 1907, when he surveyed the Uaupes River to its junction with the Rio Negro. Further expeditions in 1912–13, 1917, 1919–20 and 1924–25 resulted in an accurate survey of the tributaries of the Rio Negro and of the river itself to Manaos.

Nov. 4, 1909.—Exploration of Persia

Sir Percy Sykes left Meshed on the second part of his sixth expedition into Persia. These six expeditions were of the utmost importance for the survey of Persia, and filled in many blank spaces on its map. Sykes's travels also threw new light on ancient geography; in this sixth, 1906–10, journey he discovered the site of ancient Nishapur and also of Kishmar a spot connected by legend with Zoroaster.

Societies and Academies

LONDON

Physical Society, Oct. 21.—**F. Twyman**: New apparatus for rapid spectrophotometry of liquids in the ultra-violet. A single exposure, usually of less than 20 sec., results in a set of spectra which embodies all that is necessary for plotting an absorption curve.—**J D. Stephenson**: An experimental study of electrical discharge in gases at normal temperatures and pressures. By an investigation based on corona discharge it is shown that there is a fixed constant, the true breakdown strength of the gas, for all types of gas discharge at normal pressures.—**G. A. Tomlinson**: A new type of pendulum clock. A new method of taking accurately defined seconds signals from a pendulum is described, in which a photo-electric cell is used in conjunction with a special arrangement of multiple slits. This has been developed into a complete free-pendulum system, self-maintained *in vacuo* by means of electrostatic impulses and having a closely governed arc.—**S. E. Williams**: A photographic method of deriving optical constants of the metals. A grating consisting of alternate strips of glass and metal of known dimensions gives diffraction spectra the relative intensities of which depend on the optical properties of the metal and glass. An expression has been found for the relative intensities of the central reflected image and the first principal diffracted image in terms of the reflection coefficients for the metal and glass and the phase change on reflection from the metal surface. By means of a photometric method which is described, the intensity ratio has been measured for two or more gratings of different proportions cut on the one mirror, enabling the deduction of the reflection coefficients and the change of phase. This is done both for light plane polarised in, and perpendicularly to, the plane of incidence, and the approximate Drude formulæ are used to calculate the optical constants. Simultaneous measurements can be made at several wave-lengths if the grating is illuminated with light from a source having a suitable line spectrum.

PARIS

Academy of Sciences, Sept. 12 (vol. 195, pp. 525–532).—**N. Saltykow**: The complete integral of partial differential equations of the second order.—**Pierre Marti**: The possibility of determining the slope of the sea floor by means of acoustic sounding. When the sea floor is level the determination of the interval of time between the sound emission and the arrival of the echo gives the depth. If the sound is powerful, several echos are received and these are separated by equal intervals of time in the case of a horizontal sea floor, but if there is a slope, the intervals of time of the successive echos are not equal, and the exact comparison of these intervals can be used for determining the slope. A formula for this is given.—**V. Hourcq**: The age of the glauconitic limestones of the Antsalova region (Province of Maintirano), Madagascar. It is possible that the limestone represents only the lowest part of the Kimmeridge strata and that the greater part should be regarded as Tithonic.

Sept. 19 (vol. 195, pp. 533–548).—**J. Cantacuzène and S. Longhin**: The experimental transmission of human leprosy to the white rat.—**Louis de Broglie**: An analogy between Dirac's electron and the electromagnetic wave.—**J. Fromaget and F. Bonelli**: Materials from Angkor and some points of the stratigraphy and the geological structure of northern and eastern Cambodia.—**A. Rivière**: Contribution to the study of the Jurassic in the central Elbourz.—**L. Clariond, N. Gouskov and E. Roch**: The ancient series of the country of Skoura (Central Moroccan Haut-Atlas).—**Pierre Marty and Pierre Bout**: The discovery of a layer of fossil plants in the Pliocene formation of Perrier, near Issoire (Puy-de-Dôme).—**Jean Caminopetros and B. Contos**: The transmission of pustular fever to the guinea-pig.

Sept. 26 (vol. 195, pp. 549–564).—**A. Caillon and R. de Fleury**: Casting magnesium: use of a special sand. The addition of ammonium sulphate and powdered fluorspar to the sand used for moulds is recommended on the grounds of low cost for magnesium castings.—**A. Rivière**: The Cretaceous in the north of central Elbourz.—**Jacques Fromaget**: The Caledonian folds of the massif of Fan Si Pan (Tonkin).—**Léon Grigorakis**: The action of ether on the microplant parasites of animal tissue. Factors of virulence, vitality, degradation and mutation.—**P. Cappe de Baillon**: The thermal sensitiveness of the Phasmidæ.—**A. Magnan and Ch. Perrilliat-Botonet**: The relative weight of the motor muscles of the wings in insects—**Jonesco-Mihaiesti, A. Tupa, B. Wismer and G. Badenski**: Acute pseudo-tabetic syndrome resulting from the experimental inoculation of the filtrate of inguinal lymphogranulome (Nicolas–Favre).

SYDNEY

Linnean Society of New South Wales, June 29.—**C. Oke**: Notes on Australian Coleoptera, with descriptions of new species (2). Two new genera and thirty-five new species belonging to various families are described. Probably the most interesting species described belongs to the family Rhysodidæ, and is the first of the Australian species to be recorded as a myrmecophile.—**A. B. Walkom**: Fossil plants from Mount Piddington and Clarence Siding, N.S.W. Specimens from Mount Piddington include *Cladophlebis australis*, *Thinnfeldia Feistmanteli*, possible flowers of *Williamsonia*, and one which may be *Phyllotheca robusta* Feistmantel. From Clarence Siding a fertile specimen of a fern (?) with very long narrow pinnæ and sori of the *Asterotheca* type is described as a new genus. These plants occur near the western margin of the Hawkesbury Series basin, and it is difficult to correlate the horizon since, near the coast, the sandstone series has a thickness of about a thousand feet, but near the western margin the thickness is only about three hundred feet.—**H. L. Jensen**: Contributions to our knowledge of the Actinomycetales. (3) Further observations on the genus *Micromonospora*. A description of sixty-seven strains of *Micromonospora* isolated from Australian soils. They are divided into four species-groups, one of which seems identical with '*Streptothrix*' *chalceæ* Foulerton; the other three are described as new species. These organisms seem to occur most abundantly in neutral to alkaline soils from districts with a low rainfall.—**J. R. Malloch**: Notes on Australian Diptera (31). Certain species of the genus *Prosena* (Tachinidæ) are described, three being new. A key is given for the identification of the species of *Prosena*.

Royal Society of New South Wales, Aug. 3.—**A. R. Penfold**: The chemistry of Western Australian sandalwood oil. Conclusive and confirmatory evidence was submitted that the oil from the roots and butts yielded the best quality of oil for commercial purposes and differed considerably in chemical composition from that obtained from the stickwood. The paper was accompanied by two comprehensive tables setting forth the chemical and physical characters of each individual sample of oil together with the alcoholic bodies obtained from each by treatment with phthalic anhydride in benzene solution on a boiling water bath for two hours, as well as the yields of santalenic acid and santalol allophanate. An examination of the oil obtained from a consignment of butts said to be a fair average of the raw material used in the production of commercial Australian sandalwood oil showed it to contain more than fifty per cent of B-santalol.—**Alma G. Culey**: Ripple-marks in the Narrabeen series along the coast of New South Wales. Numerous exposures of oscillation ripple-marks have been observed over a large vertical range and wide area in the Narrabeen series (lower Triassic), of New South Wales. The dimensions of the ripple-marks and their association with plant remains, worm-burrows, and sun-cracks, point to quiet deposition of the Narrabeen beds in a very shallow, subsiding, fresh-water lake. Comparison of quantitative diagrams, indicating the directions of the ripple-marks and present-day winds, suggests that the planetary wind systems of lower Triassic time were the same as those prevailing now. Hence one may deduce that the poles were in the same position then as now.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 18, 481–523, July 15, 1932).—**Marcus M. Rhoades**: The genetic demonstration of double strand crossing-over in *Zea mays*.—**Jack Schultz**: The behaviour of vermilion-suppressor in mosaics. This factor in *Drosophila* depends on factors outside the mosaic tissues as does vermilion. Its effect seems to be exerted before the onset of pigment formation.—**George C. Vaillant**: Stratigraphical research in Central Mexico. Continuation of the American Museum of Natural History archæological work in the Valley of Mexico. It is concluded that the Teotihuacan culture was not derived from Valley groups of the Early periods, and a ceramic sequence of three periods is arranged. The Mazapan culture is dated as post-Teotihuacan and pre-Aztec.—**David Davidson and Marston T. Bogert**: Isovioluric acid (alloxan-6-oxime). Prepared by action of nitrous acid on isobarbituric acid. It is rearranged by acid, giving violuric acid and by reduction yields isouramil (5, 6-dihydroxycytosine).—**Edward W. Washburn and Harold C. Urey**: Concentration of the H^2 isotope of hydrogen by the fractional electrolysis of water. An experiment is in process at the Bureau of Standards. Meanwhile, spectrographic examination of the residues from the commercial hydrolysis of water showed there was increase in the abundance of H^2 relative to H^1.—**Linus Pauling**: The electronic structure of the normal nitrous oxide molecule. A recalculation of Plyler and Barker's data leads to a value of the moment of inertia which corresponds to a Lewis structure in which the nitrogen–nitrogen bond resonates between a double and triple bond and the nitrogen–oxygen bond between a single and double bond. The structure can be written $N \overset{=}{=} N = O$.—**Harvey Cushing**: Further concerning a parasympathetic centre in the interbrain. (7) The effect of intraventricularly injected histamine. It has been objected to the observations recorded about a year ago that the effects after intraventricular injection of pituitrin and pilocarpine were due to impurities, probably histamine. Examination of the posterior lobe extract used showed it to be free from histamine. Further, intraventricular injection of histamine produces facial pallor rather than flushing.—(8) The comparative effects on gastric motility of intramuscular and intraventricular pituitrin, pilocarpine and histamine. Pituitrin and pilocarpine do not increase gastric acidity as does histamine. When given intraventricularly, both increase motility and lead to retrograde peristalsis and vomiting; intramuscularly, they inhibit gastric peristalsis, but there is also a delayed acceleration of peristalsis with pilocarpine. Intramuscular pituitrin seems to stimulate the thoracolumbar sympathetic apparatus; intraventricular pituitrin appears to have a contrary effect, essentially parasympathetic in character.—**G. A. Miller**: Orders for which there exist exactly four or five groups.—**J. L. Walsh**: On interpolation to harmonic functions by harmonic polynomials.—**A. E. Currier**: Partial differentiation in the large.—**Chester Stock**: Eocene land mammals on the Pacific coast. The Sespe formation in Southern California comprises sandstones, shales and conglomerate. Vertebrate remains in the Simi Valley region in the maroon and green clays and sandstones of the middle division of the Sespe formation include titanotheres, rhinoceroses, artiodactyls (*Protylopus*), rodents (*Paramys*) and others indicative of the Eocene age.

Forthcoming Events

TUESDAY, Nov. 1

CHADWICK PUBLIC LECTURE—(at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1.).—Prof. Keilstra: "Hygiene in the Far East", at 5.15 P.M.

INSTITUTION OF CIVIL ENGINEERS—(Opening Meeting). Sir Murdoch Macdonald: Presidential Address, at 6 P.M.

WEDNESDAY, Nov. 2

INSTITUTION OF HEATING AND VENTILATING ENGINEERS—(at the Lecture Room, Home Office Industrial Museum, Horseferry Road, Westminster, S.W.1).—Mr. A. F. Dufton: "Radiant Heat", at 7 P.M. (open to non-members).

THURSDAY, Nov. 3

KING'S COLLEGE, LONDON.—Prof. Martin Knudsen: "Some Aspects of the Kinetic Theory of Gases", at 5.30 P.M. (succeeding lectures on Nov. 10 and 17).

UNIVERSITY OF LONDON—(Semon Lecture at the Royal Society of Medicine, 1, Wimpole Street, W.1).—Prof. Otto Kahler: "The Tonsil Problem", at 5 P.M.

FRIDAY, Nov. 4

INSTITUTION OF MECHANICAL ENGINEERS—(Thomas Hawksley Lecture).—The Right Hon. Lord Rutherford: "Atomic Projectiles and their Application", at 6 P.M.

BRITISH SCIENCE GUILD—(Alexander Pedler Lecture).—Prof. F. T. G. Hobday: "Animals as a National Asset and Responsibility", at Burton-on-Trent.

SATURDAY, Nov. 5

GEOLOGISTS' ASSOCIATION OF LONDON.—Special General Meeting in the Botany Theatre, University College, Gower Street, W.C.1, at 3 P.M.

ROYAL INSTITUTION.—Prof. E. N. da C. Andrade: "Rays and Radiations", at 5.15 P.M.

Inland Water Survey

IT was a welcome and appropriate sequel to the leading article in NATURE of July 2 last, relating to "River Gauging and Flood Prevention", that a sectional meeting of the British Association at York should have been devoted to a discussion on the organisation required for the recording of water levels and river flow in the British Isles. The discussion did not arise out of, nor was it in any way consequential upon our article—it had, in fact, been arranged some time beforehand—but it served admirably to give point and emphasis to the contentions put forward in these columns on a matter which has not hitherto received the attention and consideration which it deserves.

The meeting was held under the chairmanship of Prof. L. S. Palmer and had before it an introductory memorandum prepared by Capt. W. N. McClean, through whose instrumentality mainly the discussion at York was arranged. Capt. McClean added some opening explanatory remarks in which he directed attention to the essential value and fundamental importance of reliable records of water measurements in questions relating to water supply, water power, navigation, irrigation, fisheries, drainage and pollution, flood prevention and other matters of national and civic concern. He stressed the necessity of providing an efficient organisation to make systematic observations on scientific lines. An inland water survey should cover rainfall, storage and flow. Rainfall is already to a very considerable extent adequately cared for by the British Rainfall Organization, which has an excellent system, though perhaps it is still open to improvement in certain details. But rainfall does not afford correct information as to storage and flow, and only when these are also as efficiently recorded, can estimates be made which will be of value in dealing with problems of drought and flood. Capt. McClean's conviction is that an inland water survey should be independent of conflicting interests, private or corporate; that it should be under a Water Survey Department of a Ministry, with the supervision of an expert Government inspector over large areas; and that local associations should represent the water interests and find the observers and recorders. Funds should be provided by the water interests by means of a levy.

In the ensuing discussion various suggestions were made as to the nature of the controlling authority and these were summarised at the

conclusion of the meeting by the chairman, as follows:—(1) An organisation on the lines recommended by the Water Power Resources Committee; (2) the Geological Survey; (3) the Ordnance Survey; (4) the Meteorological Office of the Air Ministry; (5) Catchment Boards, formed under the Land Drainage Act, in co-operation with the Ministry of Agriculture and Fisheries; (6) voluntary organisations, and (7) various combinations of (1) to (6).

As regards the first suggestion, it will be recalled that the Final (1921) Report of the Water Power Resources Committee, appointed in 1918, recommended the formation of a Controlling Water Commission, to be established by Act of Parliament, the primary function of which would be "to compile proper records of the water resources and present and future water requirements of the country and to collect information on these subjects through existing Departments and other agencies, as well as through their own hydrometric staff". It is perhaps superfluous to add that nothing has been done in this direction, nor, in view of prevailing financial conditions, is anything likely to be done in the way of establishing another Government department with scope for additional expenditure. Moreover, the situation has changed appreciably since the publication of the Water Power Resources Committee's Report.

Within the last two years, the Land Drainage Act, 1930, has created a series of Catchment Boards (at present forty-six in number) to act under the Ministry of Agriculture and Fisheries, with the special duty of dealing with all matters relating to the drainage of their respective areas. As we pointed out in our previous article, although not specifically laid down in the Act, it is obviously the implied duty of Catchment Boards to gauge and survey the run-off in the streams and rivers under their jurisdiction and to obtain a reliable record of rates of flow, ranging between maxima and minima, over long periods, which will enable adequate precautions to be taken for dealing with the incidence of floods and of drought. But while the responsibility for obtaining this information, as was urged by Capt. J. C. A. Roseveare, of the Ministry of Agriculture and Fisheries, in the discussion at York, clearly lies with the Catchment Boards, the question, at once, arises: Will all these separate and distinct bodies, with their varying organisations and staffs of unequal calibre, be likely to obtain and collate the data on uniformly satisfactory and rigidly scientific lines? We are afraid not. There must be some centralised authority of high technical standing to supervise and unify the methods and systems of measurement. Otherwise, the records will inevitably tend to be of differing values.

It will be noted that suggestions were put forward to bring the observations under the control of official technical departments, such as the Ordnance Survey, the Geological Survey and the Meteorological Office. We are of opinion that the duties of these bodies are already onerous enough for satisfactory performance, and that the additional functions proposed to be assigned to them are not sufficiently germane to their existing functions to justify the expansion of their establishments. We would prefer that a properly devised scheme should be worked out in conjunction with the Department of Scientific and Industrial Research, to which should be entrusted the inauguration and supervision of operations, under the local administration of the Catchment Boards, who would be called upon to provide the staffs and the funds for the purpose, the latter being apportioned from the rates which the Boards are statutorily authorised to levy. The proposal would not by any means exclude the assistance of voluntary workers, including university students and others, who, as in the case of rainfall gauging, might be attracted to the making of observations locally, as a scientific pursuit, or hobby. Nor would it interfere with the full exercise by the Catchment Boards of their powers and responsibilities in regard to drainage and flood protection.

The speakers in the discussion at York were unanimous in affirming their conviction of the necessity for taking steps forthwith to put an end to the anomalies and defects of the present position and, at the conclusion of the proceedings, a representative committee was formed "to inquire into the position of Inland Water Survey in the British Isles and the possible organisation and control of such a survey by central authority". This is a move forward in the right direction, and if a soundly devised and workable scheme is forthcoming as the result of the committee's efforts, it should carry weight with the Government. In a matter of such pressing national importance as flood prevention, it is in the highest degree necessary to have accurate and unimpeachable records of river flow, as it is no less imperative to have them for the successful prosecution of industrial and civic undertakings in regard to water supply and hydraulic development generally.

Leeuwenhoek, 1632–1723

Antony van Leeuwenhoek and his "Little Animals": being some Account of the Father of Protozoology and Bacteriology and his Multifarious Discoveries in these Disciplines. Collected, translated, and edited from his Printed Works, Unpublished Manuscripts, and Contemporary Records, by Clifford Dobell. Published on the 300th Anniversary of his Birth. Pp. vii + 435 + 32 plates. (London: John Bale, Sons and Danielsson, Ltd., 1932.) 31*s*. 6*d*. net.

OF all the great naturalists of the past, Leeuwenhoek occupies the unique and anomalous position of being the most frequently quoted and at the same time the least appreciated and understood. An estimate of his work which is commonly expressed and accepted, even by those who have devoted some attention to the history of biology, is that he was a superficial dabbler who had no conception of scientific methods, but who hurried from one topic to another without attempting to exhaust any one of them; and that if he made important discoveries it was easy to do so, since he was early in the field, and one of the first to exploit an important new means of investigation. He is in fact compared unfavourably with his great contemporaries Swammerdam and Malpighi, both of whom successfully completed solid pieces of research involving concentrated and prolonged attention to the points at issue.

Such a criticism, however, fails to take account of the distinguishing features of most of Leeuwenhoek's work. He was not dealing with large and complex objects out of which much could be made even in those days, but with blood corpuscles, bacteria, protozoa and other small organisms which it is amazing he should have seen at all, and not that he should have failed to make more of them. His point of view was essentially that of the microscopist even when investigating the larger animals. Impressive and spectacular results, such as Malpighi's development of the chick and Swammerdam's anatomy of the mayfly, were literally impossible, and the significance of his work, to quote Capt. Bunsby, lies in the application thereof.

Against the charge of lack of tenacity, Mr. Dobell's treatise is a sufficient answer, even if we had not in mind Leeuwenhoek's laborious and long-continued attack on the spermatozoa. Then again his method of publication, or rather the lack of it, has told heavily against him. His results were communicated in the form of letters, most of them addressed to the Royal Society, which have never until recently been published in full, and have only been partly translated. The result is that much of his work is still almost unknown. For example, Mr. Dobell directs attention to Leeuwenhoek's unrecognised anticipation of the modern malariologist as to the difference in posture between Anopheline and Culicine larvæ in water, and he has translated, and now publishes for the first time, Leeuwenhoek's observations on the viviparous nature of the vinegar worm made in 1676—a discovery attributed to Sherwood in 1746.

There are inevitably many other discoveries made by Leeuwenhoek which have yet to find their place in any history of biology. The appearance of the work under review therefore is more than welcome—it is an act of justice, and the only regret we feel in respect of it is that it covers but a fraction of Leeuwenhoek's stupendous labours. Our regret is heightened by the reflection that we do not see where the completion of the task is to come from. It demands an unusual combination of linguistic and other qualifications which Mr. Dobell alone seems to possess, and, moreover, he has advanced the standard of historical research beyond the reach of most workers. He exhibits indeed to a marked degree that passion for detail and meticulous accuracy which bulks so largely in the composition of the complete scholar. It makes him a severe and occasionally a merciless critic of the work of others, but it is a guarantee of the integrity and exhaustive nature of his own inquiries.

To most zoologists, Leeuwenhoek's work on the smallest organisms, namely, the bacteria and protozoa, by its implications perhaps the most important that he did, is nevertheless not the most interesting. His observations on the blood corpuscles and capillaries, spermatozoa, Mendelian inheritance, rotifers, ants, caudal heart of the eel, *Echinorhynchus*, cestodes, compound eye, plant lice, *Cyclops*, *Hydra* and sponges, to mention only a few that come to mind, should be dealt with in the same comprehensive way as have been the bacteria and protozoa by Mr. Dobell, and until that is done Leeuwenhoek's merits can be but imperfectly appreciated by the average biologist. To complete this undertaking, however, on the scale of Mr. Dobell's investigations, and no other should be entertained, would take almost a lifetime.

May we here express regret that the Royal Society allowed to pass unnoticed the tercentenary celebrations of Malpighi in 1928, and appears to be displaying the same indifference to Leeuwenhoek in 1932. Whilst the Society deserves the highest credit for the active support it gave to these observers during their lifetime—a proceeding, be it noted, which has brought considerable honour to the Society—present councils seem to have forgotten that Malpighi and Leeuwenhoek were two of the greatest fellows the Society has ever had.

Mr. Dobell's work includes an introductory epistle to the reader, written in a quaint and charming style, all that tireless and intensive research can reveal of Leeuwenhoek's life, translations and exhaustive analyses of those of his letters which deal with bacteria and protozoa, an admirable chapter on his instruments accompanied by a plate which shows at a glance the design and manipulation of his best microscopes, and a critical estimation of his place in protozoology and bacteriology. There are minor sections on Leeuwenhoek's name, language, dwelling, draughtsmen, portraits and seals. The bibliographical chapters give details of his first twenty-seven letters, an invaluable catalogue of his MSS. and published works, which have so far been the despair of the bibliographer, but need be so no longer, and a long and exhaustive list of references and sources. The get up of the book, with its white buckram binding, sprinkled edges and title in two colours doubtless in imitation of the collected works bound in vellum, is excellent, and the plates have been beautifully reproduced. Most readers will be glad to have the admirable reproductions of Verkolje's mezzotint and oil-painting of Leeuwenhoek, of which the latter will be new to most students, and is much more convincing than the mezzotint. The enlargement of Goeree's miniature portrait has been very skilfully carried out, even to the removal of the hand of the substantial angel from the top margin. We should not have selected for reproduction the picture of de Graaf inserted at p. 40, which is apparently a somewhat poor copy of the portrait dated 1666 published in the "De Virorum", which latter has the additional advantage of being signed by both artist and engraver.

Since Mr. Dobell appeals for criticism we submit the following points for his consideration. Is not the last line but four of the Latin dedication ambiguous and liable to misinterpretation? Its meaning will be obvious to the initiated, but a literal translation of it would be libellous. P. 318: The paper by Baker dated 1740 which "must have been published considerably later" was published in 1744. P. 332: The interesting and probable suggestion that Leeuwenhoek used dark-ground illumination receives some support from the fact that Hooke described a simple type of dark-ground illumination in 1678. P. 333: Boyle, Hooke, Grew and Malpighi all made use of sections as aids to anatomical study before Leeuwenhoek. P. 350: The portrait by A. Smith is a copper and not a steel engraving. P. 364: Stelluti's plate of the bee was originally issued in 1625. Attention was first directed to this important publication by Parsons, who possessed a copy of the print and described it in 1752 as being "the first microscopical engraving that ever was made". P. 379: The term Infusoria was invented by Major in 1667 and was applied to intravenous injections. P. 379: George Adams the elder was born in 1720. P. 392 (No. 1): A second edition was published at Delft in 1694 and included letters 32, 39 and 33 in that order. P. 392 (No. 5): There *is* an edition of 1691 with the same title and publisher, but with the mispagination corrected. P. 393 (No. 13): For Londen read London. P. 413: Malpighi's "Opera posthuma" was first published at London in 1697 and this edition should be quoted. P. 415: Needham 1749 was published in 1750. P. 425, last line but one: For wo read woe. These are all small matters—of major slips the work seems to be entirely free.

We warmly commend Mr. Dobell's monograph to that section of the public, happily becoming larger every day, which is interested in the history of science. We believe that in the fulness of time this work will be recognised as one of the classics of the critical and historical literature of biology.

The New Economics

This Age of Plenty—its Problems and their Solution. By C. Marshall Hattersley. Third edition. Pp. 410. (London: Sir Isaac Pitman and Sons, Ltd., 1932.) Paper, 3*s*. 6*d*. net; cloth, 6*s*. net.

HITHERTO economics may be said to have centred largely around production, but now the centre has shifted to distribution, where the problems seem to be rather more baffling and intractable. But the world crisis, as is usually the case, has stimulated a high level of thought and

discussion, for the whole world is stirred to its depths so that the standard of emotional and intellectual activity is much higher than during the humdrum days of smooth and uneventful prosperity. Therefore we can confidently expect that a way out will be found, though some may think a return to material prosperity a doubtful blessing if accompanied by a relapse into dullness: the majority will be quite willing to run the risk. At present the mind of the nation is undoubtedly stimulated, and certain fundamental leading ideas appear to be gradually evolving out of a vast mass of animated discussion and suggestion, and are forcing their way to the front, serving, let us hope, under heaven's blessing, as a starting point for practical effort in the right direction.

Doubtless a lot of practical experiment will have to be undertaken, and possibly even a lot of mistakes made. Side by side with a firm faith that we shall ultimately succeed there must be also a high courage that will boldly try out new ideas even with the risk of temporary failure and error. It is no doubt a trite platitude to say that a nation, like an individual, that never makes mistakes and is afraid of the risk, will never achieve anything; but it seems at this time necessary to remind ourselves of the fact. More and more it becomes evident that, in the realm of economics and politics more practical experiment is urgently needed, though this cannot be faced with thoughtless light-heartedness and the difficulties are great, especially in unbiased interpretation of results. Let us hope, nevertheless, that we shall soon have a real science of experimental economics—and if the 'new' economists have their way we shall—so that the old reproach against the social sciences generally, and economics in particular, will be wiped out in triumphant ascension to the rank of true science on terms of equality with chemistry and physics, in view, too, of its increasing strength of statistical and mathematical groundwork.

On the side of production, as already suggested, the main problems appear to have been solved—if anything rather too thoroughly, largely owing to the fact that production has been placed on a scientific and rational basis. The same cannot be said of distribution and most emphatically not in regard to our financial and monetary system. This had been roundly criticised, sometimes perhaps rather wildly, but for the most part the criticism has been just, and, in view of the deplorable results of muddle-headed monetary policy, extremely restrained and moderate. A large number of interesting suggestions has been made for monetary reform, but for the present we are only concerned with those relating to Consumer Credit and the proposals made by Major Douglas, Prof. Soddy and one or two others. These have been fully and admirably dealt with in the third edition of C. Marshall Hattersley's book entitled "This Age of Plenty".

The main difficulty to-day is to increase the community's purchasing power: for production tends more and more to outstrip consumption; and with increasing mechanical and other scientific aids, increased production is consistent with constantly reduced man-power employed in industry. A careful and fairly complete analysis of the whole position, and particularly of prices and costs, leads Mr. Hattersley to support Major Douglas's proposals for Consumer Credit, which practically amount to national dividends for all. One method is to sell goods at less than cost price, the vendor recovering the balance from the State. The ethical grounds on which national dividends for all can be justified are well argued. There are not only the precedents of Old Age Pensions, Unemployment Insurance and Poor Law Relief, but there is also the further important consideration that every member of the community is entitled to a share in the rich heritage from the past, the accumulated cultural, economic and social possessions of the State. Modern production depends very largely for its efficiency on this heritage, which is something much more than capital or accumulated material savings. Every important invention, for example, has its roots in the past, and the inventor is indebted for help to hundreds or thousands of predecessors. Every member of the community therefore is entitled to some share in the product of modern industry, even if he does no work. It is not pretended that he should be idle, and this difficulty, as also that of the disagreeable menial tasks of society, and many other difficulties are ably dealt with.

Prof. Soddy, in his book on "Wealth, Virtual Wealth, and Debt" apparently agrees in principle with the Consumer Credit idea and the need for greatly increasing the supply of money, but he severely criticises the proposals of Major Douglas. Mr. Hattersley, who devotes a considerable amount of space to Prof. Soddy's ideas, is of opinion that the Douglas plan could be put into operation as a preliminary measure and that the way would then be clear for Prof. Soddy's plan to be adopted.

The whole subject is of profound interest and importance and well merits unbiased scientific examination and test. The book is well written and makes easy reading, the more so as each section is provided at the end with a synopsis of the points discussed. Many data of the statistical and blue book type are given in several appendices and there is a good and complete index.

Industrial Chemistry

Industrial Chemistry: a Manual for the Student and Manufacturer. Edited by Allen Rogers. Fifth edition. Vol. 1: *Inorganic.* Pp. xiv + 641 + xiv. Vol. 2: *Organic.* Pp. xii + 642 – 1517. (London: Macmillan and Co. Ltd., 1931.) 30*s*. net each volume.

THIS treatise on industrial chemistry was first published in 1912, and is now in its fifth edition, being divided into two volumes. Allen Rogers, the editor, has had the co-operation of nineteen experts in preparing the inorganic volume, and of twenty-two specialists for the organic part of the subject, the division being a usual one.

The book has been modernised by addition and deletion, and fresh points of view and new subjects added. Naturally such a work can only act as a first and general introduction to each and any particular section of the chemical industry, and any one requiring to go more deeply into detail will have to study other treatises devoted to one subject only, for no one man can any longer pretend to have a knowledge of the whole field of chemical industry. Hence it serves a most useful purpose, all the more so when the summary is crisp and readable and not overburdened with manufacturing details. We have examined the book particularly from this point of view, and have found it more than fulfils our anticipation that it would provide just the right amount of information; indeed we already have the feeling that it may lie permanently on our desk.

Chemical industry has advanced probably at a greater rate than any other during the last decade. Not only has there been a very great reduction in the cost of making nearly all the standard chemicals, but also numerous substances which were formerly but chemical curiosities are now made and distributed by the car load, which is the American unit of quantity. Production and substances cost as many pence a pound as they formerly cost shillings, or even sovereigns. There is progress to chronicle most of all in the organic fields; new solvents for cellulose compounds, new resins and substances obtained by polymerisation have made rapid strides and it is safe to forecast that further advances will be made in this direction within the present decade. Most of the organic chemical industry in the past has been built upon tar as a raw material, and the layman has been made aware time and again of the bright-hued dyes, the potent drugs and the seductive perfumes wrought from this dark and evil-looking material. Whilst tar itself now plays a part in the new industry of making dustless roads, the organic chemist has developed two new raw materials for his manufactures. These are the hydrocarbons, liquid and gaseous, from crude oil, and alcohol derived by fermentation of molasses or other saccharine material. Very large quantities of both these raw materials are available, far exceeding that of tar if necessary, and it is expected that in time a very large industry will be built up in the products from each of them.

The invasion of the textile industry by the chemist is also only in its infancy, and viscose and acetate silk and cellophane are but the first of future materials derived from cellulose.

The industrial chemist has the task of making new products on the grand scale, of finding applications for them, and of cheapening the cost of production, handling and transport of materials of all kinds. Amazing is the rate at which progress is made when opportunity, including ample funds, allows experience to be gained on the large scale. The oil industry has taught us how to handle gases and liquids in very large quantities; the synthetic ammonia industry has introduced high-pressure technique; rayon has given the knowledge how to make and spin synthetic fibres; first sulphuric acid and later a whole range of organic industries have developed the potentialities of catalytic reactions, of which at present we have only barely a glimpse.

An interesting chapter from the point of view of developments is that headed "Elements and Compounds", in which brief reference is made to a number of substances listed in alphabetical order. Against some of the elements is the remark "this has at present no commercial value", though in some cases the remark is already out of date. Thallium, for example, first discovered by Crookes, has now definite industrial uses, and its price has been brought down below £3 a pound. Under tungsten we read that the requirements have

increased owing to its use in automobiles and aeroplanes; tantalum has become an important factor in the modern radio set. A comparison with a similar list in the 1912 edition of the book would show the rate at which the chemist and the physicist are turning to practical use the rarest of the elements. Stone age, iron age, bronze age mark stages in the history of the world: the age when all the elements are made serviceable to man is approaching.

The American origin of the work is indicated by the fact that under the influence of the 18th Amendment the chapter on brewing was eliminated from the last edition. It is now restored, but the subject is presented strictly from a technical point of view and in no sense as an aid to home fabrication. So we read how China made its beer 3000 years before the Christian era, and how to brew temperance beer with 7–8 per cent extract and malt tonics.

Any criticism in detail of such a wide treatise is impossible—it perhaps has faults of omission and inaccuracy, but we are more concerned with the vast amount of information contained in it and the manner of its presentation in readable form, for which we accord generous praise.

E. F. A.

Short Reviews

Geology of Petroleum. By Prof. W. H. Emmons. Second edition. Pp. xi + 736. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 30*s.* net.

A DECADE of petroleum geology separates the two editions of Emmons's work, and in that time much has happened in this realm of activity. Oilfields undreamt of then have been developed in parts of the world, including America, where not even the wildest imagination had pictured them. Pools of great magnitude were located, records in depth of wells and yield of oil established, and all this time geological knowledge was being enriched. The author had no alternative but to re-write and, fortunately, to re-illustrate his book, although the grounds for criticism of the first edition have by no means been removed in the new work. It shows a sad lack of sense of proportion to accord to the descriptions of the world's oilfields four-fifths in favour of the two Americas and only one-fifth for the rest of the world. No one disputes the economic pre-eminence of the oilfields of the New World, but this should not weigh in a book of this kind purporting to establish and describe geological principles as affecting petroleum from the universal store of information now available.

Study of the smallest field in a corner of Asia may be, and frequently has been in the past, of far greater academic import than the reams of subsurface data published in connexion with a few of the giant oil-pools of the United States. Here the treatment of such fields as Germany, with its vastly informative salt bodies, Rumania, Palestine, Persia, Iraq and India, including Assam and Burma, the last six in less than twenty pages, including copious diagrams, to say nothing of the mere mention of Miri in less than a dozen lines, is futile. It does not help matters to give references alone; in a general text such as this, the international student of the subject often wants information of a field or oil district such as he would expect to find in "Emmons" comparable with this author's thorough accounts of the United States fields; that is precisely what he will not find, which is a great pity, since the book generally is an improvement on the first and, following the success of the latter, will naturally command wide attention.

The History and Work of Harvard Observatory, 1836 to 1927. By Solon I. Bailey. (Harvard Observatory Monographs, No. 4.) Pp. xiii + 301 + 23 plates. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 17*s.* 6*d.* net.

THE study of astronomy was held in considerable esteem at Harvard College from the time of its foundation in 1636. Solar eclipse and transit of Venus expeditions were undertaken even in those early days, and various miscellaneous astronomical work accomplished. It was not, however, until 1839 that the Observatory was founded, with a very meagre equipment, to be supplemented eight years later by the 'Great Refractor' (15-inch) with which so much good work was done under the Bonds. Since then the Observatory has developed rapidly (especially under the directorship of Prof. E. C. Pickering) to its present position of international fame.

The story of its development and achievements is well told by the late Prof. Bailey, whose forty-four years of service rendered him specially fitted to act as historian. The first part of his book deals with the origin and history of the Observatory, describing its progress and activities up to 1927. The second part (occupying about half the book) gives an account of the astronomical researches and discoveries made at the Observatory. These are so numerous and varied that the result rather resembles a general history of astronomy during the period considered; it is at least striking evidence of the prominent part played by Harvard in the development of modern astronomy.

The descriptions are necessarily condensed (with the result that the work of outside observers does not always appear to occupy its proper place in relation to the problems described); but nothing of importance is omitted, and the material is con-

veniently classified into chapters dealing with kindred subjects. The final section of the book gives good biographies of the directors, prominent members of the staff, and benefactors. The whole is of great interest to astronomers, both amateur and professional, and especially to students of the history of astronomy.

Das Pollersche Verfahren zum Abformen an Lebenden und Toten sowie an Gegenständen: Anleitung für Mediziner, Anthropologen, Kriminalisten, Museumspräparatoren, Prähistoriker, Künstler, Handfertigkeitslehrer, Amateure. Von Dr. Alphons Poller. Herausgegeben von E. B. Poller und E. Fetscher. Pp. xii + 216. (Berlin und Wien: Urban und Schwarzenberg, 1931.) 12 gold marks.

This book, illustrated with 129 text figures, is a very thorough guide to the technique of the improved methods of casting living subjects and dissected specimens, which were devised by the late Dr. Alphons Poller. By the use of the elastic materials known under the trade names 'Negocoll' and 'Dentocoll' it is possible to make very exact moulds of complicated objects such as human brains or the head and hands of living men with an ease and precision which it is difficult or even impossible to attain with plaster of Paris. From these moulds casts are made in 'Hominit' and 'Celerit'. Many scientific workers in the biological and anthropological fields are already familiar with these devices and appreciate the value of the boon Poller's methods have conferred upon them. In fact, it is only the high price of the new materials which has hitherto stood in the way of the wider adoption of these eminently useful devices for making records in the form of durable casts

This book gives a very detailed account of the technical processes involved in casting and will be eminently useful to all, whether they are anatomists, palæontologists, zoologists, anthropologists, medical men, criminologists, museum preparators or artists, who want to preserve exact records of the form and surface details of any object.

Elements of Engineering Geology. By Prof. H. Ries and Dr. Thomas L. Watson. Second edition. Pp. vii + 411. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1930.) 18*s*. 6*d*. net.

Probably the best departure from the first edition of Ries and Watson's well-known book is the inclusion of a chapter on the geology of reservoir and dam sites which, in view of the big water-impounding schemes put forward in various countries in the last few years, is quite useful. On the other hand, the new chapter on historical geology is superfluous; one cannot adequately condense even an outline of the subject into less than fifty pages, as here, and in any event the modern civil engineer receives instruction in stratigraphical geology as part of his training; if he requires information regarding the geological column of his country, he at least knows where to get it, and one cannot imagine the most elementary student of the subject ignoring the standard text-books in favour of this make-weight chapter. Neither, as a minor point, does it look well in a book published at the price of this, to include a new section the page numbers of which are 313a to 313t inclusive. For the rest, there is little to comment upon; the book is a typical Wiley production, full of the usual geological diagrams and illustrations well executed and printed.

France: a Regional and Economic Geography. By H. Ormsby. Pp. xiv + 515. (London: Methuen and Co., Ltd., 1931.) 21*s*. net.

During recent years a great many detailed monographs on different parts of France have been published by French geographers as well as a number of works on various aspects of the geography of France, but English students have had no comprehensive volume on the country. Mrs. Ormsby has supplied this need most successfully. Her treatment is mainly regional and written from the point of view of the geographer with economic interests, but there are also general chapters on climate, agriculture and communications.

The volume is packed with information. Every town of any size has its site and activities analysed. But the details are well arranged and the point of view so well maintained that the book reads easily and holds the attention. Numerous sketch maps are of great assistance and there are references in every chapter to the relevant sheets of French maps. There are also copious bibliographies the value of which would be enhanced if the dates of all the books were given. This volume should make a wide appeal to students of geography or indeed to any reader who wishes to understand France and French activities.

Systematic Botany of the Flowering Families in North China. By Prof. J. C. Liu. Pp. xxiv + 213. (Peiping: The French Bookstore, 1931.) 5 Mexican dollars.

Prof. Liu is to be complimented on being a pioneer in the production of a little textbook specially adapted for elementary students in North China, where greatly increased interest in the subject has been a feature in recent years. Engler's system is adopted—each family being illustrated by a drawing of a typical Chinese species which includes a floral diagram as well as dissections in every case. The descriptive part, which occupies forty pages, is lucid, terms being profusely illustrated by excellent line drawings, though the definition of a genus on p. 20 is misleading owing to an unfortunate simile. The keys to the genera are based on very simple characters, but in those families such as Gentianaceæ where flower colour has been used, they are likely to break down in some cases.

Consumption and the Trade Cycle

AT the recent meeting of the British Association at York, Prof. Lionel Robbins, professor of economics in the University of London, in a paper read before Section F (Economic Science and Statistics) on "Consumption and the Trade Cycle", made a critical examination of the 'Social Credit' proposals associated with the name of Major C. H. Douglas. The following is a short summary of this part of his argument.

Major Douglas bases the diagnosis on which his constructive proposals depend on a survey of factory costing. Consider any article of factory manufacture, he says: a nut and bolt, for example. Part of its cost consists of wages, salaries, etc.; but part consists of raw material charges, factory upkeep and similar 'overheads'. The sums distributed as *income*, therefore, are not sufficient to purchase current output. What is true of one factory is true of all. It follows, therefore, that throughout the entire economic system, there is a continuous deficiency of income to purchase the product; a deficiency which, if not made good by the continuous issue of paper money, must necessarily lead to chronic bankruptcy and confusion.

Now it is perfectly true, as Major Douglas urges, that the sums distributed as ultimate incomes—wages, salaries, rents, etc.—are insufficient to purchase the gross product of industry. *But so far from this being a cause of industrial crisis, it is in fact an essential condition of the smooth functioning of the economic system.*

This can easily be demonstrated if a capitalistic system which is in stationary equilibrium (that is, a system in which no saving is taking place) be examined with the view of discovering the conditions of the persistence of equilibrium. It should be clear that, of the total volume of payments being made at any one moment, only a comparatively small proportion is being made for the final product. The remainder goes to facilitate the movement of goods between the different earlier stages of production. That is to say, at the same time as money is being spent on bread by the wage-earner—the ultimate consumer—the baker is spending money on flour to replace the bread, the miller is spending money on wheat to replace the flour, and so on and so forth.

In order that such a system should continue in equilibrium it is necessary that these payments should be made; yet they do not go to the recipients of ultimate income. They are costs but they are not *net* income. In any computation of the *net* value produced during the unit period, such as that made in the British census of production, they will be set off one against the other. At the end, when they are thus offset, we get the value of the goods available for consumption; and for equilibrium to be preserved, it is necessary that the incomes of the factors of production should correspond only to this. In order that the same structure of production may persist from period to period, those payments in the gross income (to use the classical term) which cancel out *must* be made. It is undesirable, therefore, that a state of affairs other than that which Major Douglas describes should actually come to exist.

This conclusion becomes even more forcible if it be supposed that what Major Douglas thinks ought to happen has actually occurred. Suppose that, the quantity of money remaining the same, ultimate incomes were to be raised so as to equal the value of the gross product. What would this imply? Simply that the whole fund of free capital (amortisation quotas and working capital) had been turned into ultimate income. What would happen? Prices of ultimate commodities would probably rise; but prices of intermediate products, raw materials and fixed plant, would collapse. There would be no free capital to buy them with; there would occur all the symptoms of extreme crisis. Of course, such a state of affairs is not likely to occur. But, if wages are above the equilibrium point, it is possible for something disquietingly like it to begin to make its appearance. The illustration should at least make clear the fundamental point overlooked by Major Douglas: that once there exists what may be called *many-stage* production, it is undesirable that the money income in a given period should be equal to the value of the gross product of that period. Only in a system of hand-to-mouth, or single stage, production is it compatible with the requirements of equilibrium that the net income and the gross income should be identical.

Thus in the case most favourable to Major Douglas—the completely stationary state—his argument breaks down completely. If real accumulation is to take place—that is, if the system is to be progressive—then the refutation applies *a fortiori*. For, in such circumstances, not only must the gross income exceed the amount spent on consumption goods available by the difference between net income and gross income; it must also contain a quantity equivalent to the amount of net saving. If accumulation is to take place, there must be abstention from using all the productive power available to produce current real income at a constant rate. This involves spending some of the current money income on goods which only give rise to real income in the future.

In subsequent sections of his paper, Prof. Robbins argued that not only is there no reason to attribute industrial depression to a deficiency of consumption, but also that there is, on the contrary, considerable reason to believe that the coming of depression is due to the fact that consumption has become too high for capital extensions already embarked upon to be profitably carried through. Recent investigations, he argued, seem to make it more and more probable that booms are due to forced saving brought about by inflation of credits; and that the collapse of the

boom is due to the exhaustion of this process. It is truer to say that the depression comes because consumption is too urgent than because it is not urgent enough. We do not "starve in the midst of plenty" because we do not demand enough; we starve because, having forced the tree of prosperity, we seek to pluck its fruits before they are ripe.

It may be added that a more elaborate critique of proposals substantially similar to those of Major Douglas will be found in "The Paradox of Saving" by F. A. von Hayek in *Economica* of May, 1931.

Canadian Polar Year Expedition, 1932–33

CANADA'S part in the International Polar Year is to establish a chain of stations not more than 1400 km. apart, connecting Greenland with the United States station at Fairbanks, Alaska, and to provide special magnetic equipment at Meanook, the nearest permanent magnetic observatory to the north magnetic pole. For this purpose three expeditions have been sent out, the first to Cape Hope's Advance in Hudson Straits, 1000 km. from the nearest station in Greenland; Chesterfield Inlet on the west coast of Hudson's Bay, 1200 km. away; and finally Copper Mine on the Coronation Gulf, 1300 km. to the west, and a little more than 1500 km. from Fairbanks, Alaska. The accompanying map (Fig. 1) shows the position of these stations, as well as the regular meteorological stations in northern Canada. It may also be mentioned here that at these stations there are well-equipped wireless stations, so that communication can always be obtained with the outside world.

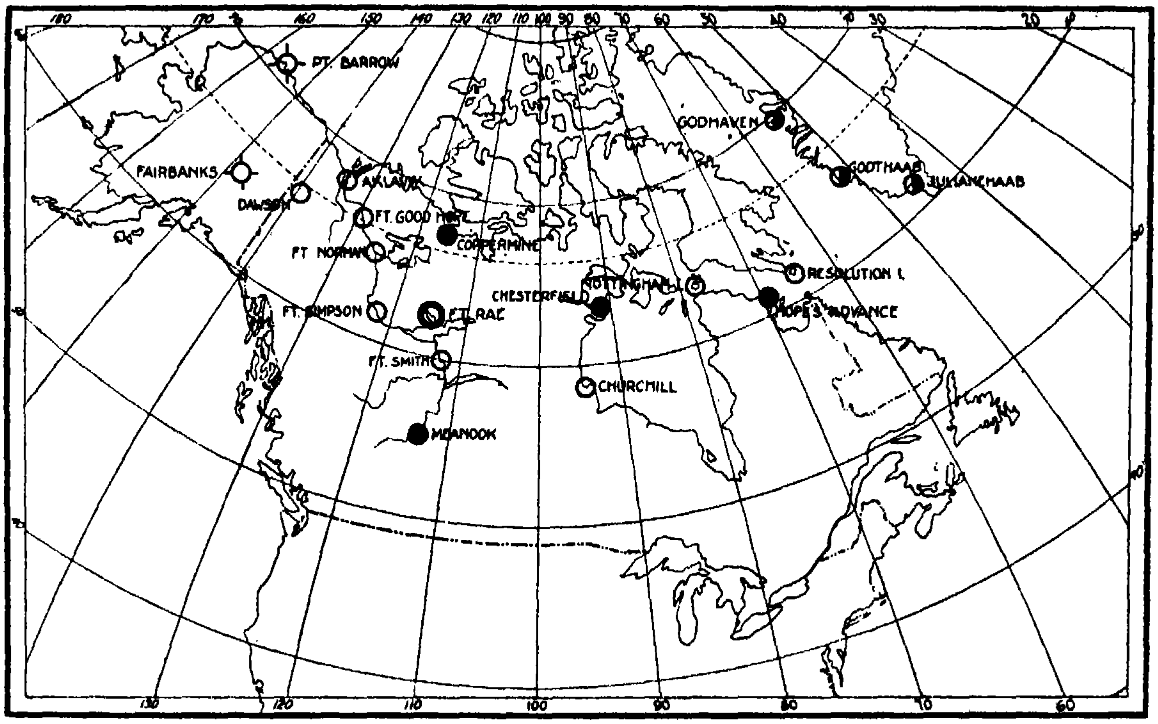

FIG. 1.—International Polar Year stations in North America and Greenland. ○, Canadian telegraph stations; ●, Canadian Polar Year stations specially equipped and manned; ◎, British expeditions; -○-, United States stations specially equipped and manned; ◐, Danish stations.

At *Cape Hope's Advance*, lat. 61° 5′ N., long. 69° 33′ W., complete surface meteorological and upper air observations, with twice-daily pilot balloon ascents, will be continued throughout the year. The auroral programme will consist of visual observations at specified hours, and as opportunity occurs photographs will be taken. The station is in charge of Mr. J. E. Lilly of Acadia University, assisted by the radio operators at the station. Cape Hope's Advance is situated on a fairly high promontory extending out into Hudson Straits, and at times very high wind velocities are obtained, the most notable being above one hundred and thirty miles an hour for one hour, and above one hundred miles an hour for several hours continuously. The temperature averages about fifteen below zero in January, while in the middle of summer it has exceeded 70°. Rainy days are frequent in June and August, frequently accompanied by fog with snow in any month of the year.

Chesterfield Inlet.—The principal Canadian station is at Chesterfield Inlet, lat. 63° 45′ N., long. 91° 50′ W., about four hundred and fifty miles from the north magnetic pole, this being the

nearest magnetic station to the pole that will be established in this international undertaking. The party is in charge of Mr. F. T. Davies of McGill University, who has had extensive experience in magnetic work on the Byrd expedition in the antarctic. He will be ably assisted by Prof. B. W. Currie of the University of Saskatchewan, Mr. Stuart McVeigh of Queen's University, and Mr. John Rea as assistant observer.

A complete set of Lacour self-recording magnetic instruments comprising nine variometers and three recorders will be installed, together with a Smith portable magnetometer, an earth inductor, and a Carnegie declinometer with absolute measurements. Advantage will also be taken of this to measure earth currents with a very complete earth current equipment. The auroral programme provides for two stations about 30 km. apart connected by radio, to measure the height of the aurora, and a McLennan night spectrograph to obtain photographs of the visible and infra-red portions of the spectrum. A complete log will be maintained of auroral phenomena, and its approximate intensity measurement with a pocket spectroscope.

As opportunity occurs, the atmospheric potential gradient will be measured by means of ionium collectors and the Patterson electrometer.

The meteorological equipment provides for full surface meteorological observations, pilot balloon ascents twice daily, kite flights as weather permits, and, on the international days, visual signalling meteorograph ascents. Continuous record of the difference in temperature between the top of the radio mast forty-five metres above the surface and the surface will be made with special thermocouples. At the same time an electrical resistance recording thermograph will give the temperature of the air at the four-foot level, and a Robitzch bimetallic actinograph and a sunshine recorder will be utilised for radiation measurements. A rangefinder has been included in the outfit to obtain the height of the cloud as frequently as possible, and the cloud observations will be made according to the programme of the International Cloud Commission. The radio operators at Chesterfield Inlet are entering very enthusiastically into the work also, and are lending very valuable assistance to the party. July is the warmest month at Chesterfield, with an average temperature of about 48°, while the coldest months are January and February, when the temperature goes to an average of 26° or 27° below, the lowest recorded being 55° below zero.

At Chesterfield Inlet there is a Roman Catholic mission which has a very fine hospital attached, a radio station, Hudson's Bay Mounted Police, and at times a doctor is stationed at the Inlet.

Copper Mine.—The third station in this chain is Copper Mine, lat. 67° 42′ N., long. 115° 30′ W., and will be in charge of Mr. R. C. Jacobsen of the University of Toronto, assisted by Mr. D. R. Kinnear and A. V. Potruff, radio operators. It will be the most important meteorological station in the system, and situated as it is on the Arctic Ocean about midway between the Atlantic and Pacific, it gives an exceptionally good opportunity to observe the influx of polar air from the arctic regions. At this station the same meteorological programme will be carried out as at Chesterfield, but in addition the Moltchanoff radio meteorographs will be used on international days, and besides recording the temperature at the top of the radio mast and at the four-foot level, it is hoped to make a special study of the cooling effect of the long winter nights and the temperature inversions.

The auroral programme will be the same practically as at Cape Hope's Advance. Visual observations will be made at definite hours and photographs taken as opportunity occurs. The meteorological station at Copper Mine has been in existence for about two years; during this time, average temperature in January is about 30° below zero, and on six occasions it fell below 40° below zero. The snowfall at Copper Mine is apparently very light, only two or three inches being recorded up to the end of January, while light rainfall occurs in April, and fairly heavy rain in July and August. This station is at the mouth of the Copper Mine River on Coronation Gulf, and is slightly north of Great Bear Lake.

Fort Rae.—Fort Rae is north of Great Slave Lake. It was the only continental station in Canada operated during the First International Polar Year, and is again occupied by the British. It is about three hundred miles due south of Copper Mine, and forms with the Canadian stations a most valuable link in the network of stations across the arctic this year. Through Fort Rae the Canadian stations are also connected with the permanent magnetic observatory at Meanock, lat. 54° 37′ N., long. 113° 21′ W., where a complete set of Lacour recording instruments have been installed. This magnetic station is the nearest permanent magnetic station to the north magnetic pole, and will be in charge of Mr. Vestine of the University of Alberta, with Mr. H. E. Cook as the magnetic observer. In addition to the magnetic work, auroral and meteorological observations will be taken as opportunity occurs.

All the Canadian stations in the arctic shown in Fig. 1 will take special meteorological and visual auroral observations. They have been furnished with a Lacour pocket spectroscope, in order that the intensity of the aurora may be estimated approximately.

It is a very great pleasure to acknowledge the loan of special equipment for this purpose from the United States Weather Bureau, the Carnegie Institution of Washington, the University of Toronto, McGill University, the Topographical Survey of Canada, the Dominion Observatory, the University of Saskatchewan, and the Department of National Defence.

The Canadian stations are among the pivotal stations envisaged in the programme of the International Polar Year Commission. The observations obtained during the present twelve months in meteorology and terrestrial magnetism at these isolated outposts in northern Canada promise to supply information long desired both by Canadian scientific services and by many investigators in geophysics.

J. PATTERSON.

Obituary

PROF. J. C. FIELDS, F.R.S.

IN the death of Prof. John Charles Fields on August 9 the University of Toronto lost one of its most renowned members and probaby its most gifted mathematician. Prof. Fields was born on May 14 at Hamilton, Ontario, in the year 1863. When quite young he displayed unusual skill in mathematics and in his university course at Toronto his brilliancy attracted much attention. Though his doctorate was taken at Johns Hopkins University, Baltimore, it was to Germany that he, like many another student from the American continent in the early days, turned for stimulus to mathematical research. There it was that he found his chief inspiration for his subject. He studied at Paris for a time but it was at Göttingen and Berlin, where he came under the influence of such leaders as Wierstrass, Klein, Fuchs and Schwartz, that his imagination was fired and the foundations laid for the creative side of his life's work.

In 1906, Fields published his famous treatise on "Theory of the Algebraic Functions of a Complex Variable", a work which at once received world-wide acclaim and won for its author immediate recognition as a mathematician of the first rank. In his conversations with me he often spoke with pride and with deep affection of the friendly part played by the late Mittag-Leffler, the renowned Swedish mathematician, in the negotiations that led up to the publication of this work.

Prof. Fields was called to the University of Toronto in the opening year of the present century. Since that time his researches and those of workers associated with him have been among the outstanding contributions to knowledge made by that institution.

In all his academic relations Fields strenuously advocated and promoted in every way open to him the claims of research. Soon after his appointment to Toronto he openly expressed the view that students desiring to specialise in mathematics came to universities in America handicapped by defective mathematical training in the secondary schools. Another handicap to which he considered the students of a generation ago were subjected both in Canadian universities and in American universities generally was that involved in the use of defective mathematical texts, more particularly of texts on the calculus. It was his considered opinion that one would not be far wrong in attributing the almost complete sterility of the mathematicians of the last generation in America to inadequate and ineffective teaching of the calculus. But all this was gradually changed. Through the efforts of Fields and of those other leaders holding similar opinions, new life was breathed into the teaching of mathematics in Canada and the United States, with the result that an ever-increasing stream of research achievement is becoming so great as to tax severely the facilities available for publication.

During the period of the War and for some time afterwards Prof. Fields was president of the Royal Canadian Institute of Toronto. Throughout his term of office he never ceased to advocate scientific research as the ideal of the Institute and to emphasise the opportunity its organisation afforded for the advancement of scientific thought. He initiated a movement in the direction of having research professorships attached to this institute similar to those now administered by the Royal Society, the Royal Institution and the Franklin Institute. From the way in which he laid his plans for the success of this project and from the manner in which he was quietly working them out I believe that had he lived but a few years longer he would have achieved his aim.

Prof. Fields was president of the International Mathematical Congress held in Toronto in 1924. It was a very successful meeting and it was largely through the financial aid personally secured by him that it and the meeting of the British Association for the Advancement of Science held at the same time were made possible. The fact that the Press of the University of Toronto was able to handle such a difficult typographical task as that involved in the printing of the "Proceedings of the International Mathematical Congress" was somewhat of a surprise to foreign mathematicians. It was only made possible, however, through the close co-operation that was maintained between Mr. R. J. Hamilton, director of the Press, and his staff on one hand and Prof. Fields with his associate editors on the other.

What I consider to be Fields's greatest achievement in advancing the cause of research in Toronto was the institution of the special annual finance grant that is made by the Legislature of the Province to the University of Toronto and ear-marked for research. The first of these grants, which amounted to more than 75,000 dollars, was made on the recommendation to the Government of Ontario of the Hon. Dr. H. A. Cody, then Minister of Education and now president of the University. I do not think I am revealing any secret in stating that this grant was secured very largely as a result of the most earnest solicitation by Prof. Fields.

One of Prof. Fields's last activities was the establishment of a fund with which to provide two or more gold medals, to be awarded by a Committee of the International Mathematical Congress at stated intervals for outstanding achievements in mathematical research. The initial sources of the fund were the cash balances remaining in the hands of the organisation committees of the 1924 Toronto meetings of the British Association and the International Mathematical Congress. His great interest in this fund

is shown by the fact that according to the provisions of his will the residue of his estate after certain annuities are paid will pass to the medal fund, which it gave him such pleasure and satisfaction to inaugurate.

Of late years Prof. Fields's life was more strenuous than the state of his health warranted. He frequently related with evident pleasure how he had just caught a tram, or train, and he often travelled by aeroplane in order to economise his time. Some twenty years ago an attack of rheumatic fever left him with health impaired, and in 1924, through carrying his luggage to the station on one of the numerous journeys made in organising the 1924 meetings, he overstrained his heart. In spite of this disability the last eight years of his life were crowded with activities. Two years ago he suffered a slight cerebral hæmorrhage and in May of this year he had a violent heart attack. He recovered sufficiently to sit up at times in a reclining chair from which he dictated letters at intervals to some of his intimate friends.

Prof. Fields was the recipient of numerous honours, but the one he valued most was his fellowship in the Royal Society of London. Quite recently the Italian Government expressed a desire to confer upon him an honour of rare distinction but this he was compelled to decline through the existence of self-denying legislation enacted in Canada at the close of the War. I should like to mention one outstanding mental gift possessed by him. It was his remarkable memory. It was my privilege to be present at a lecture given by him some years ago on "The Evaluation of π". To my astonishment he went to the blackboard in the course of the lecture and without hesitation wrote out the value of π correct to 200 decimal places.

Prof. Fields's life was spent in the cause of research. He was devoted to his friends, and I never knew anyone more pure in heart and thought or more generous in his judgments of others. With the words of one of his admirers I agree: "He has, I am sure, left behind him sweet memories with people the world over, and lucky, I think, are those who passed his way." I was fortunate in being one of that happy band.

J. C. McLENNAN.

MRS. G. P. BIDDER

THE life of Mrs. Bidder, who died on September 25 at seventy years of age, was full of beneficient activities—scientific, social and domestic. I am competent to touch only upon the earlier scientific period before her marriage when, as Marion Greenwood, she was well known to many scientific colleagues. She went to Girton from Bradford Girls' Grammar School with an entrance scholarship in 1879, when she was seventeen years old. She obtained a first class in both parts of the Natural Sciences Tripos for 1882 and 1883 and was at once appointed demonstrator in physiology to the science students of Newnham. In those days there were no lecturers in science at that college. In 1888 she was awarded by Girton College the Gamble prize for a dissertation.

In 1890 she was appointed the head of the Balfour Laboratory in Downing Place—a queer, ugly block of a building, once a chapel. How it came by so surprising a change I never heard. Some contraction in the spiritual life of Cambridge must have thrown it, a spiritual derelict, on to the market. At any rate it became the laboratory for women science students and, as Cambridge was still stirred by the genius and the tragic death of Francis Maitland the most brilliant of the Balfour brothers, it bore his name. There, until her marriage to Mr. George Bidder in 1899, Marion Greenwood was responsible for the teaching of the women science students, and herself taught.

Her research work, however, was carried out in Foster's laboratory, where physiologists and biochemists, still undivorced, habited adjacent rooms to their mutual comfort and benefit. The rooms, in order, down the little dark passage, were the homes of Sheridan, Lea, Walter Gaskell, Marion Greenwood, and beyond and through her room, in a cupboard of a place, Langley. Miss Greenwood was in a small passage room, and I shared the one bench with her. No modern Ph.D. aspirant could or would compress his or her activities into the space we were contented with in those days.

At that time women were rare in scientific laboratories and their presence by no means generally acceptable—indeed, that is too mild a phrase. Those whose memories go back so far will recollect how unacceptability not infrequently flamed into hostility. The woman student was rather expected to be eccentric in dress and manner; she was still unplaced, so far as the male in possession was concerned. Miss Greenwood, it so happened, was not only a woman of quite unusual intellectual distinction but she had also great personal charm and a great gift of comradeship. Science by no means absorbed all her interest which covered a wide knowledge of literature. She worshipped Meredith, and was a lover of Jane Austen and Peacock.

She took her share, and it was a large one, in the government of Newnham and Girton, but I am inclined to think that the best she did for women was just being her gracious and kindly self in those early days of hostility, touched as it was sometimes by a spice of active persecution.

Miss Greenwood made solid contributions to science. Her first scientific paper was on the gastric glands. The amazing story of the secretory granules, which revealed so much of the inner working of the living cell, was then being deciphered by Langley. Miss Greenwood was a histologist, and it was natural for her to join in that quest. Her paper of 1890 on the action of nicotin upon certain invertebrates also reflected

Langley's interests, but she soon struck out her own line, the physiology of the protozoa. Her papers on that subject are few but well worth reading now for she was above all an accurate observer.

Two stand out, that on the rôle of acid in protozoan digestion and that on the resting nucleus of protozoa. In the former, published jointly with Miss Saunders, an observation made at the Institut Pasteur by le Dantec was followed up and extended. He had found acid present in the food vacuoles. Vacuolar digestion the authors found always to be preceded by the secretion of acid and the acidity decreased to neutrality as digestion proceeded. The paper is in fact a noteworthy treatise on protozoan digestion (*J. Physiol.* 5, 1884).

The paper which interested me most at the time and which I still find colouring my views was on structural changes in the nucleus of protozoa. Not only can gross structure be changed but also the distribution and quantity of iron be altered by putting a 'metabolic strain' on the organism through diet or partial starvation from oxygen (*J. Physiol.* 20, 1896). Her active research career ended when she married.

W.B.H.

WE regret to announce the following deaths:

Dr. William Garnett, secretary and educational adviser to the London Technical Education Board, 1893–1904, educational adviser to the London County Council, 1904–15, and formerly principal and professor of mathematics in the Durham College of Science, Newcastle-upon-Tyne, on November 1, aged eighty-one years.

Prof. Thomas Gray, professor of technical chemistry at the Royal Technical College, Glasgow, a well-known authority on fuels, on September 26, aged sixty-three years.

Sir Bernard Mallet, K.C.B., Registrar-General from 1909 until 1920, president since 1929 of the Eugenics Society and a past president of the Royal Statistical Society, on October 28, aged seventy-three years.

News and Views

Nobel Prize for Physiology and Medicine for 1932

WE note with pleasure the honour conferred on British science by the award of the Nobel Prize for 1932 for physiology and medicine to two of our leading investigators of the physiology of the nervous system, namely, Sir Charles Sherrington, past-president of the Royal Society and Waynflete professor of physiology in the University of Oxford, and Prof. E. D. Adrian, Foulerton research professor of the Royal Society and lecturer in physiology in the University of Cambridge. In recent years it has generally been the practice to divide the prize into two parts and give them to two workers in a selected branch of medical science, but it is a rare fortune for both to fall to the lot of a single country. The chief contribution to our knowledge of the functions of the central nervous system has come to us through the researches of Sir Charles Sherrington, who by his great skill in experiment has brought the immense complexities of this subject within the range of objective analysis, revealing fundamental plan and orderly sequence in the numerous reflex actions by which the central nervous system controls the activities of the body and continually adjusts them to the environment. Some of these experiments have been presented in masterly fashion in his book on "The Integrative Action of the Nervous System" which is universally recognised as the standard work among neurologists. Until recently the mode of working of our sense organs was shrouded in mystery and capable of discussion only in psychological terminology. Prof. Adrian has performed a signal service to science in subjecting so elusive a problem to laboratory treatment. Using biophysical methods, he has, for the first time, been able to bring the sense organs and associated nerves into line with other nervous organs the function of which is better known. His book on "The Basis of Sensation" has provided us at least with a reasonable view based on laboratory experiment.

Nobel Awards in Great Britain

SINCE the foundation of the Nobel Trust in 1901, seventy-six prizes for physics, chemistry and physiology and medicine have been awarded, of which fifteen have gone to scientific men working in Great Britain. The latter are distributed as follows: *Physics*:—Lord Rayleigh (1904); Prof. (now Sir) J. J. Thomson (1906); Prof. (now Sir) William Bragg, jointly with Prof. W. L. Bragg (1915); Prof. C. G. Barkla (1917); Prof. C. T. R. Wilson (1927, jointly with Prof. A. H. Compton, then at the University of Chicago); Prof. O. W. Richardson (1928). *Chemistry*: Sir William Ramsay (1904); Prof. Ernest (now Lord) Rutherford (1908); Prof. Frederick Soddy (1921); Dr. Francis W. Aston (1922); Prof. Arthur Harden (1929, jointly with Prof. von Euler). *Physiology and Medicine*: Sir Ronald Ross (1902); Prof. Archibald V. Hill (1922, jointly with Prof. Otto Meyerhof); Sir Frederick Gowland Hopkins (1929, jointly with Dr. Eijkman); Sir Charles Sherrington and Prof. E. D. Adrian (1932).

Julius von Sachs

THE annual reception given by the president of the Linnean Society, Prof. F. E. Weiss, on October 20, was this year of special interest as it was the occasion of the presentation to the Society on behalf of a number of subscribers of a portrait of the distinguished botanist, Julius von Sachs, painted by his artist daughter Maria Sachs. It is particularly appropriate that this portrait of one of the most eminent of its foreign members should come into the possession of the Society at the present moment,

as this month has seen the centenary of Sachs' birth. In commemoration of this event, two former pupils of Sachs, Dr. D. H. Scott and Prof. F. O. Bower, delivered appreciatory addresses and gave some personal reminiscences of the great plant physiologist. Another former student in Sachs' laboratory, Prof. S. H. Vines, was unfortunately prevented by ill-health from being present but in a written address, which was read at the meeting, he dealt more particularly with the stimulus which Sachs' "Lehrbuch der Botanik" gave to the development of botany in Great Britain. There can be no doubt that, distinguished as he was for his contributions to plant physiology, Sachs was a great all-round botanist and an inspiring teacher, whose influence through the many pupils he attracted to his laboratory from all countries was felt wherever botany was studied.

Industrial Depression and Gold Reserves

A LECTURE by Dr. H. Levinstein on "World Problems of the Chemical Industry" at the Imperial College of Science and Technology on October 27 formed the first of a series of addresses in which men who have won distinction in various fields will present views on industrial affairs to students of the College. Taking the ratio of external trade to population as a measure of the standard of living of a community, Dr. Levinstein showed that more than half the world has a standard which is very much below that of Europe, although the latter is itself far from luxurious. Modern industry has been built up on the assumption that people can be persuaded to buy things which their forefathers did without, and there is no reason for believing that industrial expansion is approaching a limit. The recent setback in the development of world trade, which started with the fall in prices of primary commodities, thereby reducing the purchasing power of the agricultural community and eventually of the whole population, is, in Dr. Levinstein's opinion, a temporary condition brought about mainly by abnormal shifting of gold reserves. There is no actual shortage of available gold deposits. The trouble is due to the removal of gold from where it can perform its proper service to industry. Although the State took charge of the production of munitions during the War, it made no attempt to meet the gold payments demanded by the United States by undertaking extraction of the metal from ore, although this might have been done by working deposits of lower grade than private companies would exploit. Actually, the gold required was taken from reserves and a collapse of trade followed. It was as if a demand to be paid in bricks was met by pulling down houses.

Progressive Chemical Industry

Although gold production is of great importance to industry, as was shown years ago by the effects of the introduction of the cyanide process, Dr. Levinstein said that the human factor is always of vital significance in any consideration of industrial problems. Political economists are apt to forget that men do not always behave in a manner best suited to the furtherance of their economic interests, but are often influenced by fear and prejudice. Science alone builds continuously upon the work of previous investigators, and has a unique record of progressive development. To young men now entering the chemical industry it may seem that opportunities for making profitable discoveries and improvements are becoming less numerous, but Dr. Levinstein said he had heard such views expressed thirty years ago and considers them as false to-day as they were then. There is certainly great scope for fresh ideas and discoveries in the dye-stuff industry, and he believes that the fine chemical industry as a whole offers extensive opportunities to young chemists. Finally, further advances in biochemistry may be expected to open up vast new fields for chemists to explore. Indeed, more precise knowledge of the factors governing the growth of the living cell will undoubtedly lead to great developments in medicine.

The Aircraft Industry and Chemical Engineering

THE value of research in chemical engineering formed the substance of the first Hinchley memorial lecture delivered before the Institution of Chemical Engineers by Mr. H. T. Tizard on October 28. At first sight the aircraft industry seems very remote from the chemical industry, but developments in aeronautics have already been of great value to the chemical industry. Perhaps the most striking example of this may be found in the development of cellulose paints. The possible uses of solutions of nitrocellulose and cellulose acetate were explored on a small scale before the War, but they were first used on the large scale for the protection of the fabric of aeroplanes and balloons. During the War scientific knowledge of cellulose esters accumulated rapidly, and the manufacture of cellulose acetate was begun. The shortage of the usual solvents forced upon us the necessity of trying substitutes, so enlarging our knowledge of cellulosed solutions and preparing the way for the economic production of modern cellulose finishes. The manufacture of cellulose esters and solvents is now one of the most important branches of chemical industry.

THE strong incentive to obtain the highest thermal efficiency in aircraft engines has led to the manufacture and use of lead tetra-ethyl on a large scale. There is now an equally strong incentive to develop heavy oil internal combustion engines for aircraft. It is quite possible that this will only be satisfactorily accomplished if a suitable synthetic chemical compound can be found to promote the smooth combustion of oil when injected into the engine cylinder. Again, the economic success of air transport depends largely on the working life of an engine between overhauls, and this depends mainly on the stability of lubricating oil. The study of lubricants becomes more and more a chemical problem and in future

chemical engineers will have to produce them to precise specifications. One of the most vital problems of the aircraft industry to-day is that of the production of light alloys and prevention of the corrosion of metals and alloys. This is a matter of the widest industrial importance. There are many other ways in which the aircraft industry has already influenced the chemical industry. This influence is bound to persist, since the aircraft industry is not a self-supporting industry, and can only be made self-supporting by intensive scientific investigation of all its problems.

Site of Newcomen's Engine

As is fully recognised to-day, it was the invention of the atmospheric steam pumping engine by Newcomen that saved many mines from closing down and provided for the first time an engine capable of dealing with water in mines of any considerable depth. The first engine of which we have any record is that delineated in the print bearing the inscription "The Steam Engine near Dudley Castle. Invented by Capt. Savery and Mr. Newcomen. Erected by ye latter 1712. Delin: & Sculp: by T. Barney 1719." Two copies of this print are preserved, one in the Birmingham Public Library and the other in the Salt Library, Stafford. There is little contemporary evidence as to the site on which this engine was erected, but in a paper read to the Newcomen Society on October 19, at the Science Museum, Dr. T. E. Lones described how with the aid of documents, local histories, parish registers, rate books, etc., and a study of the geology of the district, he has been led to the conclusion that the engine stood in the parish of Tipton, under which is an inclined seam of coal some 24 ft. thick. On the Birmingham print, besides the many printed references at the side of the drawing of the engine, is the significant manuscript note: "The beam vibrates 12 times in a minute and each stroke lifts 10 gallons of water 51 yards perpendicularly." This appeared to eliminate much of the area in which the coal is found at greater depths than about 150 ft., while further considerations made it possible to determine the position of the engine relative to Dudley Castle. It is, however, probable that unless further documentary evidence, such as might be found in a copy of an old lease, is forthcoming, the exact site will remain unknown. At the conclusion of the meeting it was announced that the next meeting of the Society, on November 16, will be devoted to the reading of a newly discovered diary of the eminent engineer Joshua Field (1787–1863), while the meeting in December will be the Arkwright bicentenary meeting.

Empire Broadcasting

IT is now nearly five years since the experimental short-wave transmitter, operating on a wave-length of 24 metres, was established at Chelmsford primarily for two-way working with America. The station has since been in constant use by the British Broadcasting Corporation for experimental broadcasting to various parts of the world to enable data to be collected on the possibilities of a regular Empire broadcasting service. Following the consideration of a scheme submitted to the Imperial Conference of 1930, it was decided that the British Broadcasting Corporation should establish an Empire broadcasting station at Daventry. The construction of this station is now well advanced and it is expected that the first transmissions will take place about the middle of December. This new station is intended to provide a programme service which will reach the whole Empire at a reasonable listening time, and for this purpose the Empire has been divided into five zones comprising Australasia, India, Africa, West Africa and Canada. The present arrangements provide for a two hours' programme between 6 P.M. and midnight in each zone. Two transmitters of about twenty kilowatts rating are being installed at Daventry; these will be capable of operation on any one of a series of eight selected wave-lengths varying from 14 metres to 50 metres. These transmitters will supply a number of directional aerial systems, the actual wave-length and direction of transmission in use at any time depending upon the zone to which the programme is being sent, and the prevalence of daylight or darkness along the route. The inauguration of the service is now awaited with much interest. It is anticipated that for a period of about six months the service will be experimental and arrangements will be made to collect reports of reception from selected listeners in all parts of the Empire.

College and Faculty Dissociations

MR. A. MOORE HOGARTH, founder and chairman of the College of Pestology (Incorporated), referring to the paragraph entitled "A 'College' in an Office" in NATURE of October 22, informs us that H. W. Blood Ryan is no longer associated with this institution, and that it has had for a considerable time a laboratory, a reading-room and a museum. The registered office of the College is at 52 Bedford Square, W.C.1, and the laboratory for "Pyorrhœa and Skin Clinics" is at 233 Pentonville Road, N.1. Since receiving the above information, the Hon. Secretary of the International Faculty of Sciences has sent us extracts from the records of meetings of the Council of the Faculty held on September 19 and October 10. At the former meeting, a motion was brought forward relating to the professorial title and academic distinctions of H. W. Blood Ryan, and at the special meeting held on October 10 it was resolved that as evidence of these qualifications had not been furnished to the Council, "his resignation from the office of president and fellowship was unanimously accepted by the Council".

IN reply to an inquiry relating to this communication, Mr. Blood Ryan writes as follows: "Although I resigned all connection with the Faculty on October 10th, and the College of Pestology on September 22nd, I am bound to say that I still consider that there exists no other world-wide body attempting to do those things set forth in the prospectus of the Faculty. I was largely responsible for the addition

of the word 'International' to the title, to avoid the obvious danger of misconception which was inherent in title at the time I became associated with the body. In regard to the references to criticisms in *Truth* of the Faculty of Sciences and in your journal some years ago, of The College of Pestology, allow me to say that I am unaware of any such statements, having only joined these bodies early this year."

The Deterioration of Paper on Ageing

THE article on "The Deterioration of Paper on Ageing", which appeared in NATURE of Aug. 27, p. 320, has occasioned some comments from Mr. James Strachan, who is well known in paper-making circles. Mr. Strachan's communication is of particular interest in that it refers to the paper on which NATURE itself is printed. Before 1882 this contained a fairly large proportion of rag, but was replaced from about 1892 onwards by a mixture of esparto and wood. Mr. Strachan points out that the volumes containing rag have a marked tendency to turn brown at the edges of the sheet, whilst the issues for 1892 and 1893 are entirely free from this sign of deterioration. The latter have in fact, even now, as great a bursting-, tensile- and folding-strength as the paper used at the present time. On first consideration these facts appear to make a case for paper containing esparto as distinct from rag. As emphasised in the article, however, the methods of manufacture and storage must also play important parts, and in connexion with the former Mr. Strachan emphasises the formation of hydrochloric acid by the inter-reaction of aluminium sulphate and residual chlorides. So far as the latter is concerned, it may be stated that two sets examined by the writer of the article show distinct signs of browning at the edges even after 1893, and in one case it is extremely difficult to distinguish in this way the rag paper from that containing esparto; these happen to be volumes which are very frequently consulted. Those who possess long runs of NATURE may find some interest in making the comparison for themselves.

"A History of Fire and Flame"

IN reference to the review of this book which appeared in NATURE for October 15 (p. 562), Dr. O. C. de C. Ellis writes to say that it was impossible for him to include the many thousands of references that he had at hand. In doubtful controversies he had had regard to inherent probability, and often, in the absence of definite information, weight was given to accumulations of evidential suggestion. Dr. Ellis considers that, though we do not know that the alchemists experimented with oxygen, we can understand many otherwise incomprehensible passages, in no way interrelated, if we believe that they did. As to the tentative identification of Boyle with "Eirenæus Philalethes", Dr. Ellis still thinks that it is inherently possible that Boyle may have issued treatises under a pseudonym. Upon the material nature of phlogiston, he says that Cavendish and his contemporaries thought at first that hydrogen was phlogiston, and quotes the authority of Stillman for the statement that Stahl approved Becher's characterisation of phlogiston as of an "earthy nature". Dr. Ellis's hypothesis that the alchemists experimented with oxygen is certainly an interesting one, but we feel that more and weightier evidence is required to substantiate it. The problem of the identity of "Eirenæus Philalethes" is extremely obscure, but he was not the same as Eugenius Philalethes (Thomas Vaughan), with whom Dr. Ellis has apparently confused him. Bibliographical references on this point are to be found in Ferguson's "Bibliotheca Chemica", vol. 2, 190–7 (1906).

New International Psychological Journal

Character and Personality is the title of the most recent addition to the number of psychological journals, and it is unique in that it is to appear in English and in German (London: George Allen and Unwin, Ltd., 2*s*.). In the first number, Prof. W. McDougall has an article on the meaning of the title words. He points out the confusion in meaning attached to the word character, and discusses the more common usages. The problem has for the most part been neglected by psychologists. There is also a difference between the English and German use, the former tending to look upon it as representing the single distinctive feature of an individual, the latter as the sum total of those features, properties, or qualities of an individual organism which are peculiar to it and serve to distinguish it from other individuals. Closely allied to, and in popular use frequently indistinguishable from, character is temperament; Prof. McDougall has for years insisted on the use of temperament for the sum total of the effects on the mind of the functioning of the bodily processes, a use which is in accordance with the tradition of centuries (although that does not justify the generalisations of some enthusiasts to the effect that all mental life is entirely dependent on such processes). Workers in applied psychology have been, however, almost forced to use temperament for emotional organisation, but there is no doubt that it would be useful if we did not use character, personality, and temperament as synonyms, but made clear and scientific the implied differentiation; and for this, McDougall's article is excellent.

Physics in Psychical Research

IN the *Hibbert Journal* for October, Prof. D. F. Fraser-Harris contributes an article on what he calls the new era in psychic research. It is an account of the recent experiments with the medium, Rudi Schneider, and a summary of the results which are said to have been obtained in Paris when infra-red rays were interrupted through some agency which appeared to be connected with the medium. Prof. Fraser-Harris, in his description of some of the more startling phenomena that he has himself observed, does not seem to have cherished many doubts as to the 'super-normal' character of the occurrences. He states that there have never been suspicions of the medium himself when examined outside the latter's

home, although the facts are that the surreptitious freeing of one hand from the controllers was made the subject of heated controversy in 1924 and has been suggested many times since as the means whereby certain of the minor 'phenomena' were produced. Prof. Fraser-Harris concludes by the plea that these occurrences are worthy of scientific examination and that this demonstration of exteriorised energy opens up a new era in psychical research. He appreciates the difficulties both from the point of view of the physiologist and that of the physicist, but is of the opinion that the way is now open for the independent verification of the disputed phenomena. Certainly if the recent claims made by MM. Osty on behalf of the medium can be substantiated, then an important step forward has been made.

Life-Saving Appliances on Merchant Ships

THE Royal Society of Arts has several times given awards for inventions in connexion with life-boats and in 1878 it appointed a committee to consider marine life-saving apparatus. Its interest in nautical affairs is also shown by the Thomas Gray lectures, which were this year given by Capt. O. A. Barrand and Mr. G. A. Green on life-saving appliances on merchant ships, reports of which have now appeared (*J. Roy. Soc. Arts*, Sept. 16, 23, 30, Oct. 7). The lectures were divided into sections dealing with life-buoys and life-jackets, coastal life-boats, ships' boats, boat stowage and buoyant apparatus. The credit for the design of the "Standard" life-jacket, we learn, belongs to certain officers of the Board of Trade, but jackets can be manufactured by anyone if permission is obtained. The best jackets are now of 'kapok', which when suitably packed has a buoyancy value of 3½ times that of cork. Kapok is the seed-hair of a plant growing in the East, but only Java kapok is permitted in life-jackets. The tests for jackets are stringent and the Standard jacket has to contain 24 oz. of the best Java kapok and to be capable of supporting 20 lb. of iron after floating in fresh water for 24 hours with 16½ lb. of iron attached. The loss of buoyancy of Java kapok has been shown to be only 10 per cent in thirty days' immersion.

Annual Weather Report

THE recently published annual volume of the *Weekly Weather Report* (London: H.M. Stationery Office) is the fifty-fourth annual summary of weather recorded at official weather stations or stations maintained by private individuals in co-operation with the Meteorological Office, in which the week is made the unit of time. Until recent years, summaries of individual weeks were printed within a short time after the conclusion of each week, but since that was discontinued, advantage has been taken of the opportunity thereby afforded of presenting a whole year's data in a form that should be extremely handy for the statistician who seeks to relate agricultural statistics of crops with the weather. The week has for long been held by many meteorologists to be the ideal unit of time in agricultural meteorology, and the *Weekly Weather Report* has always aimed at being the farmer's weather report. This explains why in this latest volume the period begins on March 1, 1931, and ends on February 27, 1932, so as to cover a farmer's year. The main features of the weather of the whole year for any one of the twelve 'districts' into which the British Isles are divided are readily seen by the inspection of a few columns of figures, occupying only one-third of a page. Where the progress of events for a single place are of more interest, recourse has to be made to the weekly figures for the sixty individual representative stations, which are set out so that one page shows all the figures for one station only. In this particular volume the widespread incidence of abnormally cold and wet weather during the harvest period of 1931 over England is one of the most striking features; the general character of the phenomenon is shown by the weekly deviations of temperature and rainfall for English 'districts', and one can compare its severity at places so far apart as Durham and Jersey. The corresponding figures for Scotland and Ireland show the varying extent to which the northern parts of those countries escaped this visitation.

Radium in Great Britain

IN the Third Annual Report of the National Radium Trust and Radium Commission, 1931–1932 (H.M. Stationery Office. Price 9*d*. net), details are given of the purchases of radium by the Trust, and of the distribution of the supply by the Commission. We gather that the supply of national radium amounts to about 19 gm., excluding 4 gm. formerly comprising the 'bomb', now acquired by King Edward's Hospital Fund for London. The cost of this supply with the necessary containers has amounted to £217,937. It is noted that in spite of the stress laid by the Commission upon the necessity for the observance of the approved precautions for the safe custody of radium, avoidable losses have occurred at three of the national centres, which the Commission regards as resulting from breaches of the radium regulations. The reports deal only with administrative matters and no details of treatment are included.

Seeding of Frog-bit in Great Britain

MISS GLADYS V. HOARE writes from the Royal Holloway College, Egham, Surrey, that plants of frog-bit (*Hydrocharis Morsus-ranæ*) under observation in the Botany Garden of the College have recently set seed. This is worthy of note since the plant usually reproduces itself vegetatively by means of turions, and reproduction by seed has not been reported for Britain by such well-known authorities as Sir Joseph Hooker and Mrs. Arber. In fact, it is frequently stated that the fruit is rare in Great Britain. Mr. Wilmott of the Natural History Museum showed Miss Hoare four seeds sent to him by Miss Corfe from Glastonbury in 1926. Miss Hoare suggests a connexion between this seedling and the special condition of the summer weather, and would be glad to know whether any other naturalist has collected seeds this year.

Inhalation of Oxygen

SIR LEONARD HILL described in NATURE of September 10, p. 397, some interesting experiments bearing upon "Altitudes to be Reached by Air Pilots by Breathing Oxygen". Dr. Elihu Thomson, General Electric Company, Lynn, Mass., writes to direct attention to a paper communicated by him to the *Medical Times*, Philadelphia, of November 15, 1873, entitled "Inhalation of Nitrous Oxide, Nitrogen, Hydrogen and Other Gases and Gaseous Mixtures", dealing with the same or similar subjects. Dr. Thomson was one of the first to realise the principle, which Paul Bert experimentally and successfully tried at about the same date, of using oxygen for high altitudes.

Chance-Parsons Optical Glass

ARRANGEMENTS have been made whereby in future there will be very close co-operation between the firm of Messrs. Chance Brothers and Co., Ltd., Birmingham and the Parsons Optical Glass Company. For some time it has been evident that considerable saving in the manufacture of optical glass could be effected by pooling the knowledge of the two firms and by concentrating the production in one establishment. Under this arrangement all optical glass will be made at Messrs. Chance's Smethwick Works under the joint supervision of the present manager, Mr. W. N. Wheat, and of Mr. H. C. Rands, who, under the leadership of the late Sir Charles Parsons, has been largely responsible for the development of the Parsons Optical Glass Company.

Announcements

LORD MACMILLAN has agreed to succeed Lord D'Abernon as president of the National Institute of Industrial Psychology. Lord D'Abernon, who has had to resign owing to pressure of other engagements, succeeded Lord Balfour in 1930.

THE eighth annual Norman Lockyer lecture of the British Science Guild will be delivered by Sir Frank Smith in the Goldsmiths' Hall, Foster Lane, London, E.C.2, on November 22, at 4.30 P.M. Sir Frank will speak on "Industrial Research and the Nation's Balance Sheet".

THE Priestley Medal of the American Chemical Society has been awarded to Dr. Charles L. Parsons, formerly chief mineral chemist and chief of the Division of Mineral Technology of the United States Bureau of Mines, Washington. Dr. Parsons has been secretary of the Society for twenty-five years.

SIR ARTHUR EDDINGTON will deliver an address on "Physics and Philosophy" under the auspices of the British Institute of Philosophy at University College, Gower Street, W.C.1, on Tuesday, November 15, at 8.15 P.M. The chair will be taken by Bertrand Russell. Tickets can be had on application to the Director of Studies, University Hall, 14 Gordon Square, W.C.1.

THE fourth Liversidge lecture founded in accordance with the will of the late Prof. A. Liversidge, of the University of Sydney, will be given before the Chemical Society in the Medical Lecture Theatre, The University, Edmund Street, Birmingham, on November 25, at 5.30 P.M., by Dr. F. W. Aston. The title of the lecture is "Physical Atomic Weights". Admission is free, without ticket.

AT the annual general meeting of the Cambridge Philosophical Society held on October 24, the following officers of the Society for the ensuing session 1932–33 were elected: *President:* Prof. A. Hutchinson; *Vice-Presidents*, Mr. F. T. Brooks, Dr. F. H. A. Marshall, Dr. F. W. Aston; *Treasurer*, Mr. F. A. Potts; *Secretaries*, Mr. F. P. White, Dr. J. D. Cockcroft, Dr. H. Hamshaw Thomas; *New Members of the Council*, Prof. D. Keilin, Mr. J. A. Steers, Mr. M. H. A. Newman, Mr. P. M. S. Blackett.

AT the annual general meeting of the North-East Coast Institution of Engineers and Shipbuilders which was held on October 28, the following awards were made, among others: Institution Gold Medal in engineering to L. J. Le Mesurier and R. Stansfield for a paper entitled "Combustion in Heavy Oil Engines"; and the Institution Gold Medal in shipbuilding to Dr. F. H. Todd for a paper entitled, "Some Measurements of Ship Vibration".

MESSRS. W. HEFFER AND SONS of Cambridge have issued a new catalogue (No. 393) which will be a useful reference list for libraries, institutions and collectors. It includes transactions of learned societies, library editions and standard books in literature, historical, scientific, oriental and general, English and foreign; and its 154 pages comprise 2786 entries.

A COMPLETE Index of twenty volumes of the *Transactions and Proceedings of the Geological Society of South Africa* (vol. 14 (1911) to vol. 33 (1930) inclusive) has been prepared under the auspices of the council of the Geological Society of South Africa and is now available on application to the Assistant Secretary, Geological Society of South Africa, Box 1071, Johannesburg, Transvaal, South Africa, at a cost of 25*s.* a copy.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A chemist and manager of the Wood End Sewage Disposal Works—The Borough Engineer and Surveyor, Town Hall, Burnley (Nov. 7). A senior assistant civil engineer for steel and reinforced concrete structures and a junior and a senior civil engineer for civil engineering works in the Government of Northern Ireland—The Principal Establishment Officer, Ministry of Finance, Stormont, Belfast (Nov. 10). A lecturer in physics and mathematics at the College of Technology and Art, Rotherham—The Director of Education, Education Offices, Rotherham (Nov. 12). A lecturer in mathematics at the Huguenot University College (University of South Africa), Wellington—The Registrar (Dec. 15). A junior assistant metallurgist at the Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

'Protective' Adaptations of Animals

IN a recent issue of NATURE,[1] "B. P. U." makes the following challenging statement: "The whole of the book is full of examples—most carefully collected and thoroughly analysed, and represents an array of arguments of which selectionists will find it very difficult to dispose." Unfortunately, the book[2] to which reference is made is not yet available here, but it would appear from the information given by "B. P. U." that the claim made in this quotation is not supported by the facts. While it is evident that the book contains a vast array of statistical data on the contents of birds' stomachs, no mention is made of a similarly exhaustive survey of the food that was available to the birds, and, in fact, it is inconceivable that such a survey could be made adequately. When the statistical data deal only with the contents of birds' stomachs, and there is no quantitative information about the available food, how is it possible to claim that "The principle of proportional predation is exhibited so clearly and forcefully that a discrimination in the choice of prey by birds—is shown to be simply non-existent"? The examination of the stomach contents of birds, by itself, can give no evidence for the existence of "proportional predation", and so such work can throw no light upon the process of natural selection.

The arguments given by "B. P. U." appear to be based upon the generally accepted hypothesis that an adaptation must confer a general benefit upon a species if it is to be selected. Some years ago I showed[3] that this hypothesis is not only unnecessary, but is misleading, and is the cause of much of the criticism to which the theory of natural selection has been subjected. For selection it is necessary that mutant individuals should possess an *immediate* advantage when competing with their normal fellows, but this is all. For example, let us suppose that 'warning coloration' appears as a mutation. For the displacement of the original by the mutant type it is merely necessary that some one of the many species of natural enemies should occasionally fail to attack an individual on account of its 'warning coloration'. So long as the original and mutant types competed, this *relatively* greater survival value would be maintained, so that eventually the original would be displaced by the mutant type. After this displacement, the reduction in the intensity of the attack of the natural enemy that acted as selective agent would tend to increase the density of the species. Thus it is likely that natural selection would increase the number of individuals of the prey-species available to those natural enemies that are unaffected by the 'warning coloration'. Why, then, claim that the presence of 'warningly coloured' insects in the stomachs of large numbers of birds proves that this 'protective adaptation' could not have been preserved by natural selection?

When the selection of improved adaptation reduces the severity of the action of one of the controlling factors, this merely *tends* to increase the population density. Actually, such selection disturbs a complex system of interacting equilibria, and the position at which balance is re-established may be quite different from what one would expect from a knowledge of the direct effects of the adaptation. For example, suppose that a population of foxes is held in check by the availability of rabbits, and that mutation causes the appearance of some foxes that are more efficient in finding rabbits than are their normal fellows. Clearly, the mutant type will eventually displace the original type of fox, but what is the result? The fox population now searches with increased efficiency, thus reducing the population density of rabbits. But the individual foxes need just as much food as before, so, since there are less rabbits to eat, the population density of foxes must be less than it was originally. So natural selection itself may reduce populations.

This view of natural selection is clearly dependent upon the belief that animal populations exist in a state of balance, which, it may be remarked, does not necessarily mean that animals maintain constant population densities. This belief is often disputed, but it is supported by general observation, and by such experiments as have been carried out under suitable conditions (c.f. Chapman,[4] Holdaway,[5] Pearl[6]). Also, we know that competition is of the greatest importance in limiting populations, and in a forthcoming publication I shall show, with much more evidence than I have already[3] given, that this necessarily leads to balance. Natural selection merely selects; it does not produce the 'balance of Nature' by causing the properties of each species to balance those of the environment, as appears often to be supposed. Nor does it necessarily favour the success of a species, but merely gives an *immediate* advantage to the more perfectly adapted individuals over their less perfect brethren.

MY review[1] of McAtee's work[2] on the effectiveness of so-called 'protective' adaptations in animals was written to direct the attention of naturalists to a unique accumulation of facts bearing on a problem which it has become customary to regard as solved in accordance with certain preconceived dogmas. That the paper in question does deserve this attention is proved by the replies and comments aroused by my review. Although the review contained only a brief and almost verbatim representation of the chief facts and conclusions reached by McAtee and not of my own views (which, I admit, are close to his), the critics did me the honour of addressing their replies to me, and I feel bound to answer them, while I hope that McAtee himself will not fail to express his views on the criticisms offered.

Prof. Poulton's[3] comments refer to a particular point (birds' attacks on butterflies), which is scarcely touched upon by McAtee and not discussed at all by me. The allegation that I am "willingly misrepresenting" the opinions of others is based on a

sentence in my review which was taken almost verbatim from the original paper.

Prof. Huxley[4] commits a fundamental fallacy in ascribing to me the views I have never held or expressed. He discusses the problem of adaptations in general and maintains that each particular adaptation is partial and relative. I have given Prof. Huxley no reason for thinking that my views on this point are different, but these obvious generalities have nothing to do with our problem, namely, whether the so-called 'protective' adaptations in animals deserve that name by protecting the animals from being attacked by enemies and to what extent. Figures quoted by McAtee supply some most interesting data in this direction and they show that the numbers of insect species found in birds' stomachs are roughly proportional to their numbers in Nature. This is a definite fact and one cannot dispose of it by quoting an imaginary example of the number of would-be wrecked ships, which, in Prof. Huxley's opinion, should be in proportion to the number of ships of the respective type.

With reference to ants as a classical example of "specially protected" animals, Prof. Huxley appears to have overlooked the figures I have quoted, namely, that more than three hundred species of American birds (out of the total number of about eight hundred species including non-insectivorous ones) feed on ants and some of them consume thousands of individuals. This cannot be interpreted to mean that "most birds" reject ants and that ants are particularly immune from their attack. It is interesting in this connexion to quote another paper by Cott[5] who has found that ants constitute more than 90 per cent of the food of frogs. In face of such facts, the whole elaborate theory of 'ant-mimicry' as a protective adaptation assumes the aspect of a beautiful fairy-tale.

Much more serious and well-founded criticism of McAtee's statements and conclusions can be found in the first paragraph of Mr. Nicholson's letter above, in which it is pointed out that a mere accumulation of data on the contents of birds' stomachs, without a similarly exhaustive survey of the food that was available to birds, cannot be considered as evidence of proportional predation. It is fair to state that Mr. Nicholson's letter was based only on my review and not on the original paper by McAtee, who himself stresses the same point and admits the approximate value of his figures, which serve merely to indicate roughly the correlation between the 'protective' adaptations of animals and the degree of protection they confer on their bearers. No such correlation appears to exist and this fact cannot be ignored.

The rest of Mr. Nicholson's letter represents a most typical example of attempting to solve biological problems by logical reasoning based on purely theoretical assumptions. This type of argument, starting with "let us suppose" and continuing with what would happen as a logical result, does not appeal to a naturalist who values facts more than philosophical discussions. The great problem of natural selection has always served as a favourite subject for such discussions, but it is time that attempts were made to elucidate it by an unbiassed accumulation of facts.

To conclude, I should like once more to direct the attention of biologists to McAtee's paper. Not all of his conclusions will be found acceptable to everybody, but an immense amount of valuable facts is there. These facts can be analysed from various points of view and perhaps different conclusions will be reached, but to disregard them would be unscientific.

Hyperfine Structures of Antimony Lines and the Nuclear Moments of Antimony Isotopes

THE hyperfine structures of a number of Sb II lines in the visible region have been investigated by me. As a light-source was used a lamp of the mercury arc type, and Fabry-Perot etalons, silvered by Dr. Ritschl's process,[1] in conjunction with a Zeiss three glass prism spectrograph served to resolve the fine structures. Aston[2] has found that antimony has two isotopes of mass numbers 121 and 123. The hyperfine structures lead to the assignment of a nuclear moment corresponding to $I = 5/2$ to the more abundant isotope Sb^{121} and $I = 7/2$ to the isotope Sb^{123}. No relative shift in the fine-structure patterns of the two isotopes has been observed.

The splittings of the terms show a similarity with those of terms of corresponding configurations of other spectra and indicate that in the gross structure *the coupling is more of the J–J type. Of all the* configurations the (sp^3) seems to have the largest interaction with the magnetic nucleus, since of all the observed terms the $(5s\,5p^3)\,^3D_3$ term shows the largest splittings, namely, 3·05 cm.$^{-1}$ and 2·23 cm.$^{-1}$ for Sb^{121} and Sb^{123} respectively. Prof. R. J. Lang very kindly allowed me the use of his unpublished data on the gross structure of the spectrum Sb II, and the interpretation of the hyperfine structures has been helpful in modifying and extending these to some extent.

The structures of some of the arc lines in the ultraviolet have also been investigated using a Hilger reflecting echelon in addition to Fabry-Perot etalons silvered by Dr. Hochheim of the I. G. Farbenindustrie. Details are being sent in for publication in the *Zeitschrift für Physik*.

Influence of Light on Paramagnetic Susceptibility

RECENTLY C. J. Gorter,[1] continuing the experiments of Bose and Raha on the change in the susceptibility of paramagnetic ions under the action of light, has demonstrated, in a manner which may be considered definitive, that the observed diminution in paramagnetic susceptibility is to be attributed, according to the Curie-Weiss law, to the rise of temperature of the solution produced by the absorption of light.

In an analogous research carried out last year by me,[2] by Quincke's method of capillary ascension, and measuring the displacement of the liquid column under the influence of the magnetic field by means of an arrangement including a photoelectric cell connected with a galvanometer through an amplifying audion circuit, I predicted the difficulty of separating the Bose effect from the thermal effect, both in the same sense, and the latter certainly stronger.

Experiment confirmed this prediction, since the change in susceptibility which I observed when the light of a mercury arc was concentrated on a solution of chromic sulphate, *a change which increased with the time*, could not but be interpreted, as I interpreted it, as due to pure thermal effect.

I also succeeded, however, in bringing to light another fact: a very small increase of magnetic susceptibility of the solution, which manifested itself immediately the solution came under the influence of light, and rapidly disappeared, to give place to the variation of opposite sense due to thermal effect. Of this increase in susceptibility it is difficult to give a plausible explanation: given the characteristic of variability in the magnetic moment of the ions of the first transition series, a characteristic which is bound up with the presence in the solution of complex ions, the facts might perhaps point to some influence of light on the concentration of such ions.

Crystal Structure and Dehydration Figures of Alkali Halide Hydrates

MEASUREMENTS of the cell dimensions of sodium bromide and sodium iodide dihydrates have been made by means of Weissenberg and oscillation photographs about the crystallographic axes. The results are as follows:

$NaBr.2H_2O$. Monoclinic. $a = 6{\cdot}59$, $b = 10{\cdot}20$, $c = 6{\cdot}51$ A.u. $\beta = 112{\cdot}5°$. $a : b : c = 0{\cdot}646 : 1 : 0{\cdot}638$. The probable error is about 0·5 per cent. The axial elements given by Groth[1] are $a : b : c = 0{\cdot}6469 : 1 : 0{\cdot}6335$, $\beta = 113° \ 13'$. The number of molecules per cell is 4. The density calculated from these values is 2·28; in the literature[2,3], the values given are 2·34 and 2·165 at 16·8°C. The halvings observed are $(h01)$ when h is odd and $(0k0)$ when k is odd. Hence, the space-group is $C_{2h}^5 - P2_1/a$.

$NaI.2H_2O$. Triclinic. $a = 6{\cdot}85$, $b = 5{\cdot}76$, $c = 7{\cdot}16$ A.u. $\alpha = 98°$, $\beta = 119°$, $\gamma = 68\frac{1}{2}°$. Hence $a : b : c = 1{\cdot}190 : 1 : 1{\cdot}243$. The probable error is about 0·5 per cent. The number of molecules per cell is 2 and the space-group $C_i^1 - P\bar{1}$. The density calculated from the above values is 2·67, whilst that given in the literature[3] is 2·448 at 20·8°C.

Both substances are deliquescent, and it is difficult to free the crystals from adhering mother liquor. This probably explains why the formula given by Favre and Valson[3] was $NaI.4H_2O$. The X-ray measurements show that this formula is improbable, because the minimum volume occupied by all the atoms in the unit cell would be 266 cubic A.u., whereas the actual volume is 230 cubic A.u. The density determination by these authors is also probably in error because of the same difficulty.

The structure of $NaCl.2H_2O$ has not yet been investigated because it decomposes rapidly at ordinary temperatures but work on it is in progress.

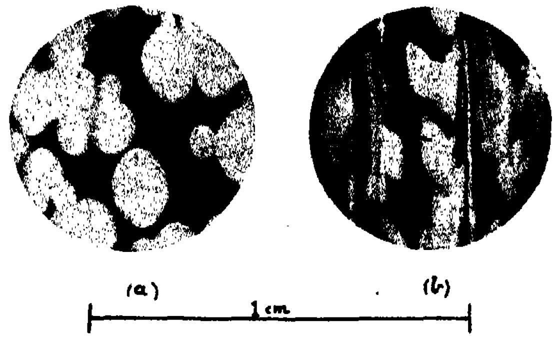

FIG. 1.—Dehydration figures of (*a*) $NaBr.2H_2O$ (20 hours over calcium chloride) and (*b*) $NaI.2H_2O$ (4 weeks over calcium chloride).

Both the hydrates show well developed dehydration figures when allowed to stand over calcium chloride for about twenty hours in the case of the bromide and for four weeks in the case of the iodide. The dehydration starts at points on the surface and spreads out forming very shallow white elliptical patches. Photographs are shown in Fig. 1. It is hoped that a full account of this work, together with the relation of the dehydration figures to the crystal structure, will shortly be published in the *Zeitschrift für Kristallographie.*

Magnetic Constants of Benzene, Naphthalene and Anthracene Molecules

IN a recent communication[1], I have shown how, by a correlation of the principal susceptibilities of a diamagnetic crystal, with those of the constituent molecules, it is possible to determine the orientations of the molecules in the crystal. Conversely, where the orientations are already known from X-ray measurements, we can calculate the molecular magnetic constants from those of the crystal. The principal susceptibilities of naphthalene and anthracene molecules, calculated in this manner, are given in the following table. Two of the magnetic axes of the molecules lie in the plane of the benzene rings, one along the line joining the centres of the rings and the other perpendicular to this line. The third axis is normal to the plane of the rings. The susceptibilities along these axes, per gram molecule, are denoted by K_1, K_2 and K_3 respectively. The values for the benzene molecule, which are also included in the table, have been calculated (in the

Molecule	$-K_1 \times 10^6$	$-K_2 \times 10^6$	$-K_3 \times 10^6$
Benzene	37·3	37·3	91·2
Naphthalene	39·4	43·0	187·2
Anthracene	45·9	52·7	272·5

absence of magnetic data for the crystal) from

measurements on magnetic double refraction and on light scattering in the liquid state; the calculation is possible since the molecule may be assumed to have an axis of symmetry.[2]

It is remarkable that the numerical increase in susceptibility as we proceed from benzene to naphthalene and from naphthalene to anthracene is practically confined to one direction, namely, that which is normal to the plane of the molecules.

Also the normal to the plane is an axis of approximate magnetic symmetry; the ratio of the susceptibility along this axis to that in perpendicular directions increases from 2·4 in benzene to 4·5 in naphthalene and 5·5 in anthracene. It would be of interest to verify by measurements on molecules with continually increasing number of benzene rings in a plane, whether this ratio would reach a limiting value; and whether the limiting value would coincide with the observed value (about 10) of the ratio for carbon in graphite.

Efficiency of the Geiger-Müller Counter

WITH reference to the letter by Dr. J. C. Jacobsen in NATURE of October 15, I am glad to note that the experiments referred to confirm results obtained by me two and a half years ago by the same method[1], namely, that the efficiency of the Geiger-Müller counter increases at first as the voltage is increased and finally approaches unity.

To this previous result I may now add that the efficiency of the counter does not vary when the thickness of the wall is very markedly reduced; which proves that the discharge in the tube is actually due to the direct ionisation of the primary cosmic rays and not to some softer secondary radiation generated by the primary rays in the wall of the tube.

This was shown by the following experiment: three Geiger-Müller counters were placed one above the other with their axes in the same vertical plane; the middle counter had its wall formed by an aluminium leaf only 7 μ thick and was enclosed in a glass cylinder (in which the air was exhausted to a pressure of 7 cm. Hg) of large diameter, so that a secondary particle generated in the glass had but a small probability of entering in the counter. A brass tube 1 mm. thick could be brought to cover the counter or be moved away by inclining the whole apparatus. The frequency of the triple coincidences was in both cases practically the same.

Secondary Radiation Produced by Cosmic Rays

ON August 12, the date on which Regener obtained his very high-altitude cosmic ray data, using self-recording apparatus carried by a balloon,[1] measurements were made on a mountain-top in the Himalaya at an altitude of about 19,500 ft. The results of these measurements indicate clearly that the ionisation of gas in an ionisation chamber is due at least in part, if not entirely, to a secondary radiation produced in the walls of the chamber and other surrounding media, by cosmic radiation.

The apparatus used consisted of a Lindemann electrometer with a thin-walled aluminium ionisation chamber and six screens of different materials. The screens were made as nearly as possible of equal size and weight so that the mass per unit area was the same for all. The screens should, therefore, according to the usual assumption, have had equal absorption effects. Readings taken with and without screens surrounding the ionisation chamber show that the presence of a thin screen of heavy metal actually increases the rate of ionisation, while the effect of a paper screen is to decrease the rate of ionisation.

The following table gives the results obtained for the six screens used:

Various Shields Used.	Time for Given Voltage Drop.
With no Shield	100 seconds
Paper Shield	104·4 ,,
Aluminium Shield	100·6 ,,
Zinc Shield	92·3 ,,
Iron Shield	100·5* ,,
Iron Shield	92·1 ,,
Copper Shield	92·8 ,,
Lead Shield	82·0 ,,
Iron over Lead (Double) Shield	79·0 ,,
Lead over Iron (Double) Shield	82·3 ,,

* The iron shield was the first to be used so that the first value, 100·5 sec., may have been obtained before the sensitivity of the electrometer became steady. The lower value is probably more nearly correct.

It will be noticed that the heavier metals produce the greater positive effects. Presumably increasing the thickness of the screens would increase the effect, though of course in each case within definite limits. The mass per unit area of the screens used is about 0·9 gm./cm.

The above results may help to explain the discrepancies between the high altitude curves obtained by Kolhörster, Regener, and Piccard, for it is obvious that the density and thickness of the ionisation chamber walls must have a considerable effect on the shape of the curves obtained by different instruments. This is probably especially true at very great altitudes.

Retention of Moisture by Wood

IN many respects, wood behaves as a hydrophilic swelling gel. Thus, the specific volume of the wood water aggregate at various moisture contents has been measured on extracted spruce wood flour by Volbehre[1] and found to be less than that given by the simple volumetric proportions of the two components, from the dry state up to about 20 per cent moisture content (based on the dry weight of the wood). That is to say, volumetric contraction is observed as nearly as experimentally possible up to the fibro saturation point. Again, Pidgeon and Maass[2] have measured the vapour pressure isothermals of spruce and found the typical curves for a swelling gel. While the former experiment points to the existence of a loose

chemical bond between the water and the wood, the latter authors draw the conclusion that all the moisture above about 2 per cent is held by capillary forces due to the curvature of the water menisci in the micellular structure.

Experiments are being carried on at this Laboratory in the hope of distinguishing between these two effects. If the moisture below the fibre saturation point is retained by capillary action, then, when wood flour is completely flooded by water under a high vacuum, the capillary menisci will no longer exist and, on this hypothesis, any experiment designed to detect an attraction between the wood and the water would yield a nul result. If, however, the retention is due to surface adsorption, it should be observable even in this case of complete immersion.

Sitka spruce flour (60–80 mesh) is dried to constant weight in a high vacuum over phosphorus pentoxide and flooded with evacuated sucrose solution of known concentration. (In certain cases, the wood, after evacuation, was given an initial moisture content by being put in vapour communication with distilled water.) The amount of water leaving the solution in favour of the wood is calculated from the change in refractive index of the solution as measured, by comparison of the solutions before and after being mixed with the wood flour, on a Rayleigh interference refractometer. Changes in refractive index occurring in the sixth place of decimals may be measured, the adsorption usually affecting the fourth place. The corresponding concentration changes may be measured accurately to about 0·002 per cent, the adsorption affecting the concentration by an amount in the order of 0·1 per cent.

This method, details of which will be published later, has the advantage over cryoscopic methods such as that of Newton and Gortner[3] in that it is applicable over a range of temperatures and that changes in concentration required for measurable results are very small.

The preliminary results, carried out at room temperature (19°–21°C.) and corrected as accurately as possible for the refractive index of the wood extractives are as follows.

Solution Concn. (gm. water in 100 gm. solution).	Initial moisture content of flour.	Adsorption as per cent of dry weight of flour.
70·3	zero	19·5
	11·4 per cent	19·1
81·0	zero	21·3
84·4	zero	20·2
	12·2 per cent	20·4
90·5	zero	19·0
	13·5 per cent	20·0

Average, 19·9 per cent.

The figures from which these averages are taken range from 18·2 to 21·6 per cent adsorption, though with improvement in technique this variation is being reduced.

If sugar is adsorbed as well as water, the true water adsorption will be greater, not less, than the apparent adsorption calculated above. Since no sensible difference has been found between the results for varying proportions of solution and flour, or for varying concentrations of solution, the adsorption of sugar may be taken as very small—this point is receiving further attention. Sucrose was chosen as control solution because, since the natural extractives of the wood frequently contain carbohydrates, the probability of further chemical action between the wood and the solution is remote.

A few adsorption experiments have also been made on Whatman filter paper, which show an adsorption of 10·0 per cent. These adsorption measurements will be repeated on standard cotton cellulose.

The fibre saturation point is that point on the vapour pressure isothermal above which the moisture content becomes independent of the external vapour pressure, that is, the point at which the curve becomes virtually parallel to the moisture content axis. On the isothermals of Pidgeon and Maass, this point is reached at about 24 per cent for spruce and at about 12 per cent for cotton cellulose (both measured in vacuo at 23°C.). For spruce these are probably the most reliable measurements available.

The results of the present experiments are of interest in indicating that, under complete immersion, a quantity of water, almost equal to that held at the fibre saturation point, is retained by the wood under the action of non-capillary forces which are great enough to overcome the attraction of sugar for water in solution. From this we may infer that wood, holding water against a lowered vapour pressure, and not immersed, will also do so by the same forces. That these non-capillary forces are due to true surface adsorption appears most probable from these experiments.

When the capillary radii, required to account for capillary adsorption, are calculated for spruce, the values obtained[2] run from about $4{\cdot}5 \times 10^{-8}$ cm. to $3{\cdot}8 \times 10^{-6}$ cm. according to the vapour pressure. Since the lower of these values is so near the radius of the hydrogen molecule, there seems to be some doubt about the applicability of thermodynamical capillary laws in this instance and the explanation of the vapour pressure isothermals in terms of surface adsorption up to, or near, the fibre saturation point seems preferable.

Adrenal Cortical Extracts and Sex Changes

THAT there is a relationship between the adrenal cortex and the sex functions has long been inferred from clinical observations, although until recently there has been little direct experimental evidence to support this view.

Corey and Britton[1] found that precocious maturation of sex glands of young albino rats followed the injection of extracts of the adrenal cortex, prepared by the method of Swingle and Pfiffner.[2]

Connor[3] with the rat, and more recently Cleghorn[4] with the mouse have been unable to confirm this, however.

We have also been unable to demonstrate any effect of the injection of Swingle and Pfiffner's extract on the sex function of the mouse. The extract used (which was kindly supplied by Mr. N. Evers), was 'Eucortone', prepared by Messrs. Allen and Hanbury. As has been shown in this laboratory, Eucortone is capable of keeping completely adrenalectomised cats alive for long periods.

We found that the daily injection of 0·5 c.c. of Eucortone subcutaneously failed to produce precocious maturity in female mice as judged by the weight of the animal and time of opening of the vagina, compared with that of controls, and also did not affect the normal course of œstrus in the adult female. No difference was observed between male mice receiving injections of Eucortone, and controls receiving the same amount of saline.

In view of the evidence of Connor[3], Asher and Klein[5] and others that aqueous adrenal cortical extracts are potent to produce experimental sex changes, the suggestion that the adrenal cortex secretes two distinct hormones must be seriously considered.

Natural Melody

ON the evening of October 8, I was at Angmering-on-Sea, and my host, Mr. Kenneth Barnes, called me to listen to the wind playing, and took me to the bathroom, which faced down wind. The wind was blowing hard and gustily, and was producing a most amazing effect—exactly as though a flageolet were being played by a human performer.

The melody was in E. major, with A♯ substituted for A♮, and it ranged over five semitones, of approximate frequency 1290, 1448, 1625, 1824, 1932. The melody did not slur up and down, as when the wind whistles through a cranny, but changed by sharply defined steps from note to note. The melody included runs, slow trills, turns and grace notes, and sounded so artificial that I felt bound to open the window and make sure that the tune was not being played by a human performer out of doors.

The sounds were traced to the overflow pipe of the bath, through which air was rushing in at the rosette (of six holes, each 9 mm. diameter, set in a circle) covering the inner end of the pipe where it joined the bath.

Next morning I examined the pipe. It was about 3 cm. in diameter, and about 3 ft. 5 in. long, in the form of an S-bend, of which the lower portion passed through the outer wall, and ended in an open mouth. The natural frequency of the pipe when blown into by mouth was about 161—that is, three octaves below the keynote of the scale previously indicated. Evidently the wind was playing on the 7th, 8th, 9th, 10th and 11th overtones of the pipe, and the melody was being produced by the rapid fluctuations of wind-pressure.

I wonder whether such an effect can ever have occurred in Nature?—a broken bamboo stem, for example, partially obstructed at its windward end, and so 'shielded' by vegetation, soil, etc., as to produce a pressure difference between its open ends?

The effect of elaborate melodies thus produced without human intervention would be highly magical and suggestive.

Higher Vibrations of Chladni Plates

THE Chladni plates in use at the present time for producing nodal lines are ordinarily made of brass, ten inches square (or ten inches in diameter if circular) and one eighth or one sixteenth of an inch thick. They are set in vibration by drawing a violin bow along the edge perpendicular to the plate. If the plates are any thinner than one sixteenth of an inch, the pressure of the bow will tend to distort the plate and the resulting figure will be unsymmetrical. Using a slight modification of a valve oscillator described before[1], I have succeeded in getting symmetrical figures upon brass plates one thirty-second and one sixty-fourth of an inch thick. The plate is balanced at the centre upon a small cone attached to the vibrating diaphragm of a loud speaker. A brass plate any thinner than these will bend under its own weight and distort the figure.

The two symmetrical sand figures shown in the illustration (Fig. 1) were produced upon a brass plate

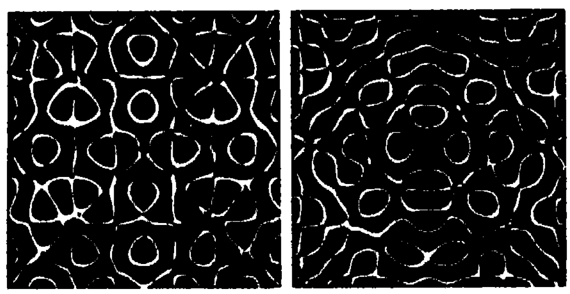

FIG. 1.

one thirty-second of an inch thick. It is possible to obtain hundreds of symmetrical nodal patterns by varying the note of the electric tube. The patterns become more and more complicated as the pitch of the note is raised. These thin plates will break into nodal patterns at very high frequencies.

Prof. Andrade has also invented a vacuum tube oscillator for Chladni plates.[2] He uses a magnetic coupling instead of the mechanical coupling described here.

Research Items

Medicine Men in Nyasaland.—The Rev. T. Cullen Young describes in *Man* for October the contents of lists of the materia medica of three medicine men, two belonging to the Tumbuka-Kamanga and one to the Tonga tribe of Nyasaland. The material is all written, two-thirds of it by men of education, the 'changing' African. It is to be noted that even in the case of the educated, the spell, which it might have been expected would be eliminated by education, continues to exist side by side with remedies, herbal and other, of a more material nature. The practitioners recognise and treat ordinary disease, such as pneumonia, epilepsy, syphilis, colic, rheumatism, etc., as well as others which we should call extraordinary, such as averting the death of a child if the mother becomes pregnant while nursing, or the evil effects of intercourse with a menstruating woman. The number of ailments or matters treated in the respective lists are 20, 21 and 97, the larger figure in the third list, however, being due to a great extent to method of arrangement. In the last list, also, matters connected with sex, prominent in all, largely preponderate, more than fifty per cent being connected with this subject. Methods in the prescriptions vary widely. Medicines may be taken externally or internally, worn inside the clothing, around the neck, smeared on an inanimate object or concealed in the ground. They may be held beneath the tongue and spat out as certain words are uttered. Sunrise or sunset is the favourable time for taking them. In only one prescription is there any reference to invocation—in connexion with the ceremony of "closing the grave". For a person lying under bewitchment, the remedy is not only applied to the body by rubbing, and worn, but also, when it is no longer required, its ingredients must be bound up in the cloth in which it is worn and "thrown away into running water along with a piece of iron".

Sex Affiliation.—Mr. F. E. Williams, Government anthropologist in the Territory of Papua, discusses in the *Journal of the Royal Anthropological Institute*, vol. 62, pt. 1, a form of social classification by which male children are classified with the father's group and female with the mother's group. At present this classification has been found only among the Koiari-speaking group of the central division; but its distribution may be wider, though this is not at present known. Racially the Koiari, though speaking a Papuan language, are mixed with the Melanesians. The names of the groups are related only to the group and not to villages. Nor are the groups totemic or exogamic. They are best described as local groups, of which the membership is ultimately decided by residence and by participation in group life. Within the family and local group descent is virtually patrilineal. Property is inherited by sons from their fathers. With the female offspring, the position is not so clear. They are brought up by and reside with their fathers, and in some cases are spoken of as belonging to their father's group, while there is evidently a strong tendency to patrilineal descent. Nevertheless they are constantly said to belong to their mother's group; and they inherit their mother's property. The affiliation, however, with the mother's group only holds good for one generation back, and really means that a daughter belongs to her maternal uncle's group. Her mother may belong to quite a different group. If marriage is by purchase the price goes to the father, but is shared with the maternal uncle, unless the *nubagha* (that is, cross-cousin in any degree) has been married, when no purchase price is paid. Exchange and purchase marriage are both practised, though the former is regarded as the ideal. It is possible, therefore, that sex affiliation means that the return of the girl to her mother's group was the normal course when marriage was by exchange with a cross-cousin, and that it still persists, although marriage is no longer restricted by the cross-cousin relation.

Coat Colour and Eye Colour in Rabbits.—Further interesting studies of coat colour and eye colour in rabbits have been made by Prof. W. E. Castle and Dr. Paul B. Sawin (Carnegie Inst. Publ. No. 427). From crosses between the English and Dutch types of colour marking, Castle has produced the French breed known as Blanc de Hötot, which is entirely white, except for a ring of coloured fur around the eyes, and has brown eyes. His experiments indicate that the breed was originally produced from such crosses by a cross-over between the closely linked genes for English and White-Dutch pattern in an individual which was heterozygous for both. It is further concluded that rabbit genetics do not support the conception of step allelomorphism. In the general coat colour series six allelomorphs are now recognised, including three shades of chinchilla. Breeding from blue-eyed chinchillas and various other types it is found that the iris colour and coat colour series are parallel except that the darkest chinchillas have the lightest blue eyes. It is not yet determined whether in dark chinchilla the blue eye is due to the same allelomorph as the coat colour, or to a separate but closely linked gene mutation. The presence of independent modifying genes affecting only iris colour and producing in some cases a 'pseudo-brown' eye is also shown. These experimental results should be of considerable help in the analysis of the inheritance of eye colour in man.

The Primordial Germ-cells of *Sphenodon*.—A contribution to the history of the germ-cells in Reptilia is made by M. Tribe and F. W. Rogers Brambell (*Quart. J. Micr. Sci.*, 75, Pt. II, pp. 251–282, 11 text-figs., 2 pls., 1932) who have examined the embryos of *Sphenodon* collected by the late Prof. Dendy. The primordial germ-cells originate in this animal in the yolk-sac endoderm of the area opaca all round the embryo but chiefly in a crescentic area in front of it. They are recognisable before the differentiation of the medullary plate, being characterised by their large size (as compared with all the other embryonal cells) and by their contained yolk-spherules. These germ-cells migrate through the yolk-sac endoderm and mesoderm, apparently by amoeboid movement, and many of them enter the blood-islands and the sinus terminalis. They enter the embryo either passively in the venous blood-stream or actively by migration through the extra-embryonal endoderm and splanchnic mesoderm into the lateral walls and the mesentery of the mid-gut. The germ-cells in the

vessels penetrate the walls of the latter and migrate, along with those from the lateral walls and mesentery of the mid-gut, to the germinal ridges. Many germ-cells, especially those travelling in the blood stream, are carried to other parts of the embryo and ultimately degenerate and disappear. The primordial germ-cells enter the forming germinal ridges before the single-layered coelomic epithelium covering the latter has begun to proliferate. Having reached this position the germ-cells lose their yolk-spherules and enter on the prophase of the heterotypic division.

A New Family of Coleopterous Insects.—Mr. Charles Oke has described a new family of small beetles from specimens found in nests of an ant at Belgrave, Victoria, where they appear to be living as inquilines (*Proc. Roy. Soc. Victoria*, vol. 44, 1932, pt. 1). The name *Aculagnathus mirabilis* gen. et. sp. nov. is given, while the title of Aculagnathidæ is applied to the new family which they represent. The most peculiar feature respecting these insects is seen in the highly specialised mandibles, each with a long thin process on its outer edge. When the jaw is moved, the process protrudes beyond the labrum, and is evidently used for piercing the prey. The labrum is also in the form of a process, and, with the labium below, forms a kind of open sheath for the processes of the mandibles. The affinities of the family are obscure, but in their tarsal characters they bear resemblance to the Lathridiidæ.

Formation of Dungeness.—The theory that the foreland of Dungeness was formed by the deposition at the meeting of opposing tidal currents has long held sway. Mr. W. V. Lewis has now challenged this tidal current explanation (*Geog. J.*, October) and explains at length his theory of the formation of the headland, based on both historical evidence and observation on the ground. He finds that the last considerable depression of the land in the neighbourhood of Dungeness was the Neolithic depression. At that time there was no headland and the area of Romney Marsh was an inlet of the sea. Mr. Lewis traces the growth of Dungeness to elevation of the land accompanied by the heaping up of shingle ridges by the prevalent south-west waves. He shows how the seaward end of the hard resistant Battle Ridge to the west of Dungeness marks the beginning of these shingle ridges, which formed first in its lee. Each new ridge as elevation continued swung round more to the south to face the waves. From the thirteenth century onwards, depression seems to have set in but so gradually that the ridges were built up as the sea level rose and at the same time driven inland. These are the main points in the explanation, which enters very fully into the history of the various ridges and the shoreline.

Vowels in Italian Words.—When it is recalled that the same phrase spoken by different voices can be clearly distinguished as different, the complexity of even the physical phenomena of speech is not surprising. The necessity for dividing them into the simplest elements is apparent, and since the vowels can be non-transient they have been the first elements of speech to be studied in detail. By the aid of oscillograph and electrical apparatus, studies similar to those made of the vowels of English, American, German and French have been made of Italian vowels by A. Gemelli and G. Pastori in the Psychological Laboratory of the Catholic University of Milan and have recently been reported to the Congress of Psychology at Copenhagen (August, 1932). In addition to the study of single vowels spoken, whispered or sung by various voices either intermittently or continuously, special attention has been given to the modification in a vowel when it forms part of a word or phrase. When a person emits a vowel continuously in a normal tone of voice, oscillograms are obtained in which the same wave-form may be repeated unchanged several hundred times. When the production is intermittent the central part of each vowel record is formed of repetitions of the same characteristic wave-form. When the vowel forms part of a word the oscillogram of the vowel contains a variable number of repetitions of the characteristic wave-form depending on the importance of the vowel in the particular word, together with repetition of a less complex wave-form similar to the same vowel sung. It is suggested that in natural speech the typical wave-form of each vowel is repeated only the smallest number of times necessary for recognition. When all other conditions are unchanged this is found to vary with the same vowel in different words. It is well known that the number of vibrations necessary for the perception of pitch of a pure tone depends on the frequency and the intensity, but it is not easy to apply these results to the recognition of a vowel or other complex sound.

New Experiments on Superconductivity.—McLennan and his co-workers have recently found that the temperature at which superconductivity appears is lower for high-frequency alternating currents than for direct currents. Further experiments on these lines have now been described (*Proc. Roy. Soc.*, October). The substances used were lead, lead-bismuth alloy, tantalum, and tin. The new feature of the present work is the superposition of high frequency and direct currents in the same specimen. A small resonant circuit made entirely of tantalum, or of tin wiped upon constantan wire, was immersed in a helium bath, alternating current of frequency 12×10^6 was induced in the coil and direct current was led in by wires. The resistances to high frequency and direct current disappeared simultaneously at a temperature which lay between the high frequency and direct current critical temperatures. The critical temperature for direct current was thus lowered by the superposition of the high-frequency current, and the critical temperature for high-frequency current was raised by the superposition of direct current.

Settling of Colloidal Suspensions.—The settling of colloidal suspensions under gravity was first studied by Perrin, who obtained a simple logarithmic law for the equilibrium distribution; and his law when modified by a repelling force of van der Waals' type between the particles was in good agreement with later experimental results. More recent work led to the conclusion that the equilibrium concentration became uniform with increasing depth. In the experiments reported by McDowell and Usher (*Proc. Roy. Soc.*, October) the principal feature is a very close temperature control for the avoidance of convection currents. The necessity of this was shown by the fact that the gold sols which had 'settled' in the thermostat became apparently uniform again when removed to an ordinary room.

The experiments indicate that the equilibrium distribution agrees with the simple Perrin law even when the settling layer is 9 mm. deep and the greatest concentration of particles is 10^{12} per c.c.

Mixtures of Ferrous and Manganese Silicates.—A paper by J. H. Andrew and W. R. Maddocks read before the Iron and Steel Institute in September showed that the equilibrium diagrams of the systems $MnSiO_3-Fe_2SiO_4$ and $FeS-Fe_2SiO_4$ are of the eutectiferous type with limited solubility at each end. The melting point of $MnO.SiO_2$ is given as 1305°C. and this substance can hold at the eutectic temperature of around 1170°C. not more than about ten per cent of the iron silicate in solid solution. The eutectic contains about sixty per cent of $2FeO.SiO_2$. From the pure iron silicate to the mixture with ten per cent of the silicate of manganese the melting point appears to rise, but the exact constitution of the mixtures in this range of composition still awaits further elucidation. It is of interest that mixed silicates of the composition referred to have very definite crystallisation temperatures, and do not, as is often assumed, pass through a semi-viscous or plastic state at any stage during the solidification. The $FeS-2FeO.SiO_2$ diagram is also eutectiferous. The eutectic melts at around 1000°C. and contains some fifty per cent of each constituent. The solubility of Fe_2SiO_4 in ferrous sulphide is extremely small, being given as approximately one per cent. About twelve per cent of ferrous sulphide, on the other hand, may dissolve in the silicate. The melting point of the latter is 1130°C., that of ferrous sulphide 1160°C. and of manganese sulphide 1620°C.

Astronomical Topics

Origin of the Solar System.—*Scientia* for September and October contains articles on this subject by Dr. A. C. Gifford of the Dominion Observatory, Wellington, New Zealand. He begins with a résumé of previous work on the subject. In reviewing that of Sir James Jeans, he should have explained that the suggestion that the sun at the time of appulse was highly distended, nearly filling the present orbit of Neptune, was afterwards withdrawn, and replaced by the view that the sun was not much larger than at present, and that the other star approached within the distance of Mercury. There is also an erroneous statement that Jeans dated the approach of the other star as millions of millions of years ago; this should read thousands of millions.

Dr. Gifford is an enthusiastic follower of the late Prof. A. W. Bickerton, who advocated stellar impacts to explain novæ and the birth of planetary systems. Most astronomers consider that such impacts would be far too infrequent to explain novæ, of which some forty or fifty are observed in a century, and probably many faint ones are missed. But this objection is of less weight when the impacts are invoked to explain planetary systems, as these may, for all we know to the contrary, be extremely rare in the universe. Indeed, both Dr. Jeffreys and Prof. Luyten have in recent years adopted the view that the approach of the two stars was so close that their outer portions actually collided. Dr. Gifford prefers to go a stage further, and to assume that the impact was so nearly central that the greater portion of the two stars coalesced to form our present sun, while the tidal filaments raised on both of them would be the origin of the planets. More exact computations are needed than those given in the articles, but some the theory of a nearly full impact seems to have advantages, compared with that of a grazing one.

The Distance of Nova Persei and Nova Ophiuchi.—Dr. Spencer Jones's researches on the distance of Nova Pictoris encouraged him to investigate the two novæ mentioned above. The parallax 0·011″ is often quoted for Nova Persei; this was deduced by assuming that the large expanding nebulosity seen some months after the outburst was due to the spread of illumination from the nova. In the *Observatory* for September Dr. Spencer Jones points out (as Newcomb had done before) that the above parallax involves the assumption that the nebulosity is at the same distance from us as the nova; if the nebulosity is nearer than the nova a smaller parallax results. He deduces a new parallax from the much smaller expanding nebula discovered by Barnard in 1916; this is assumed to be an actual expansion of a shell of gas with a speed (deduced from the spectroscopic measures) of 1110 km./sec. A parallax of 0·00205″ is found, implying a distance five times as great as previously assumed, and an absolute magnitude at maximum of −8·3. A different method was used for Nova Ophiuchi. The interstellar calcium lines in this star gave a velocity differing by 24 km./sec. from that resulting from the usual supposition that this gas is at rest in space. This assumption only holds for regions not very distant from the sun; beyond this region galactic rotation produces a differential velocity. The mean distance of the intervening gas is taken to be half the distance of the nova; a parallax of 0·00029″ results for the latter, so that it is seven times as remote as Nova Persei. This seems to be the most distant nova observed (except those in the spiral nebulæ) and the only one for which this method can be applied. The absolute magnitude at maximum comes out −5·5, which is considered reasonable.

New Minor Planets EA_1 and HA.—E. de la Villemarque, S.J., who has constructed tables for calculating the perturbations of minor planets by Jupiter, has now published (*Astr. Nach.*, No. 5898) coefficients of the perturbation terms in the case of the planet EA_1, now named Amor. It belongs to the same group as the planet Hungaria, so the tables for this group could be utilised; these tables should aid in the recovery of the planet when it again approaches the earth.

A telegram from the I.A.U. Bureau reported the following observation of the planet 1932 *HA* at Königstuhl; Oct. $7^d 2^h 42{\cdot}4^m$ U.T.; R.A. $8^h 22^m 0^s$; N. Decl. 23° 36′, mag. 15·5. Daily motion $+ 1^m 36^s$ 0′ in Decl. The telegram asked for the observation to be controlled, but as the position and motion are close to the predicted values, it seems likely to be right; if so, the observation will be valuable for improving the orbit, as the arc of observation in April and May was too short to give very exact elements; the brightness should remain nearly constant for some time, as the planet though receding from the sun is approaching the earth.

Fourteenth International Physiological Congress

THE members of the Fourteenth International Physiological Congress assembled at Rome on August 29 in circumstances embarrassing to the law-abiding scientific worker. The approaches to the Campidoglio, where the inaugural session was to take place, proved to be guarded by several cordons of police. After passing a close inspection by a civilian official and, at the doors of the Sala di Giulio Cesare, a final check by two imposing flunkeys, those delegates who had not forgotten their cards of membership were able to hear speeches of welcome by the Governor of Rome, the Minister of Education, and others. An inaugural address by Prof. A. V. Hill should have closed the proceedings, but the Congress was unexpectedly honoured by the appearance of Signor Mussolini, who, in a few graceful phrases, extended to the Congress the welcome of his Government.

Prof. Hill, relying on the existence of advance printed copies of his address, earned the gratitude and admiration of many by curtailing severely the academic sections of his speech; bringing incidentally into deservedly greater prominence some timely comments on the "intolerable burden of the literature" under which physiologists, no less than other scientific workers, sweat and groan. "The days are already too short, to read all that appears in print." With bluntness tempered by his usual good humour, he discussed the unnecessary multiplication of papers and pointed to the two major causes of the nuisance —self-advertisement by younger men, whose advancement depends all too often on the weight of paper they have sullied with printer's ink; and, in some countries, profit-making by publishers and owners of scientific journals. All journals should be owned and controlled, he insisted, by scientific societies, and he recommended that the Congress should appoint an international committee forthwith to consider the publication and cataloguing of physiological and biochemical papers. Not only in writing about our work, but also in speaking about it, he further insisted, we too often waste our opportunities and the time of our colleagues at scientific meetings. "There is no excuse for telling busy people in fifteen minutes what they could perfectly well read in five. . . ."

The inaugural meeting finished before lunch, and the remainder of the day was spent in visiting the excavations at Ostia and bathing at the famous Ostia Lido; the serious work of the Congress began on Tuesday, when four parallel sections were held morning and afternoon, each session being composed of six to twelve papers having some central theme in common. A reception offered by His Highness the Governor of Rome at the Palazzo dei Conservatori concluded the activities of the second day. On Wednesday, in addition to the morning and afternoon sessions devoted to the presentation of original papers, Prof. P. Karrer delivered an address to the Congress entitled "Uber Carotinoide und Vitamin A"; and the evening was the occasion of a banquet given by the organising committee of the Congress at the Hotel Excelsior. At the banquet, consisting mainly of Italian dishes, excellently served, and admirably adapted to the heat of the evening, speeches were made by prominent physiologists from all parts of the world, congratulating the Organising Committee on the excellence of its arrangements.

Thursday was a holiday from all scientific discussion and the Congress journeyed to Tivoli, where it spent a peaceful day in the delightful parks of the Villa Adriana and the Villa D'Este. The Friday afternoon sessions were preceded by a lecture given by Prof. I. P. Pavlov on the more recent work of his school ("La Physiologie de l'activité nerveuse supérieure"). He spoke in German to a large and deeply interested audience.

On Saturday morning a party of members of the Congress was received in audience by the Pope, and, in the afternoon, the concluding session was held in the Royal Academy of the Lincei. After a short speech of welcome by the president of the Congress (Prof. Bottazzi), Profs. Barger and Mansfeld (the former in Italian, to the envy of his colleagues, and the amazement of those who were unaware of his linguistic reserves) conveyed the thanks of the members of the Congress to Prof. Bottazzi and the Italian Organising Committee, and the appreciation of the magnitude of their task. Prof. Pavlov, in the name of the Russian physiologists, then invited the International Physiological Congress to hold its fifteenth meeting in Russia: this invitation was accepted with acclamation. Prof. Frank then proposed that the succeeding Congress, in 1938, should be held in Germany: this also was agreed to. Members of the Congress then visited the picture galleries until it was time to cross the road to the Farnesina Palace, where the Royal Academy of Italy held a reception. In the absence of the president, Senator Marconi, the vice-president received the guests.

On Sunday, a party left for a three days' visit to Naples, and its Marine Biological Station. Excursions were arranged for those who were unable to take part, but wished to remain in Rome another day.

Any detailed description of the subject matter of the four hundred papers communicated to the Congress would be out of place here, and is rendered unnecessary by the publication of the *Proceedings* in book form by the Organising Committee. Some notion of the activity of physiologists in different fields during the past three years may be obtained from the following summary of the subject matter of each of the thirty-one sessions of the Congress.

2 Sessions each:	Circulation, muscle, central nervous system.
1½ Sessions each:	Carbohydrate metabolism, general chemistry, internal secretions, vitamins, physical chemistry.
1 Session each:	Respiration, enzymes, fat metabolism, general metabolism, nerve, blood, digestion, pharmacology, special senses, reproduction, plants and bacteria, cellular physiology.
½ Session each:	Kidney, immunity.

(4 Sessions unclassified. Two half-sessions counted as one session throughout.)

An analysis of the nature of the communications reveals two interesting characteristics: the relative predominance of work of a chemical or physical nature, and the absence of any advance of a notable

kind in any quarter. Consequently, if we are to mention any particular paper rather than any other, the choice must, of necessity, be made more or less at random, and be influenced as much by our own personal interests, as by the intrinsic merit of the work itself. Indeed, the great difficulty that we found in preparing a review of the scientific proceedings which should be of interest to physiologists in general—we very early abandoned the attempt to make it of interest to workers in other branches of science—has convinced us that the wrong type of paper was presented. An international congress, meeting triennially, besides giving opportunity for personal contacts and private discussion—as was emphasised by Prof. A. V. Hill, in his opening address—should consist mainly, if not entirely, of reviews of the progress made in the last three years. These should be of interest to workers in all branches of physiology. Such a limitation in scope would do much to relieve the present congestion of space-time.

A number of new technical methods have been introduced since the last Congress. In the realm of cellular physiology there is the centrifuge-microscope of Newton Harvey (Princeton), with which he has been able to measure the interfacial tension at the surface of living organisms by observing a cell being pulled into two parts by a known centrifugal force after injecting a drop of oil. Then, in the realm of muscle physiology, there is the method of von Muralt (Heidelberg) for observing the changes in the anisotropic properties of striated muscle during a single twitch by recording the Fizeau-Foucault bands: further developments of this technique will be awaited with great interest. Lastly, in the realm of cardiology, there is the di-electrograph of Atzler and Lehmann (Dortmund). This is an instrument for recording the output of the heart in human subjects. Two plates are placed, one on the subject's chest and the other on his back; they thus act as a parallel plate condenser and the capacity between them is greater at the end of diastole, when the heart is full of blood, than it is at the end of systole. These changes in capacity are arranged to affect the frequency of an oscillating circuit, and the changes in frequency are recorded as deflections of an oscillograph after suitable detection and amplification. No suggestion is made that the records are quantitative, since much of the blood expelled at each systole is retained in the pulmonary circulation, but the shape of the di-electrograph record appears to be constant for any given subject under given conditions, and it seems probable that variations in this shape may have diagnostic significance.

The number of communications concerned with muscle physiology reflected the unusual activity which has characterised this field of work during the last few years. E. Lundsgaard (Copenhagen) reported the results of a more exact study of the phosphagen breakdown during activity of muscles poisoned with iodoacetic acid. The strict proportionality between phosphagen breakdown and energy released in a series of isometric twitches (ΣTl) earlier reported by him, is confirmed in all cases where the muscle is not too severely fatigued. The energy released never exceeds that which would be derived from the chemical reaction in question. In later stages of fatigue, extra energy is released and this has now been traced by Lundsgaard to the hydrolysis of adenylpyrophosphoric acid.

F. O. Schmidt (St. Louis) reported measurements on the effect of stimulation on the oxygen consumption of nerve, leading to the important result that stimuli too small to produce an action current also fail to produce an increase of oxygen consumption. A neat demonstration of this was achieved by choosing stimuli within the range of magnitude over which reversal of the direction of the current affects considerably the magnitude of the action current induced. The extra oxygen consumption was found to be proportional to the action current.

Kato and his co-workers (Tokyo) reported their successful isolation of single nerve fibres from a nerve trunk such as the peroneal or sciatic, and their observation that the effect of stimulation depends upon the size of the fibre. The contractions of muscle fibres innervated by such a fibre obey the all-or-none relation.

The study of 'chronaxie' continues steadily. Lapicque (Paris) read a paper introducing the term 'metachronosis' to indicate the changes in the time relations of excitable tissues in the same way that metamorphosis indicates the changes in their anatomical form. Such metachronosis may be due to toxic agents, such as curare; or it may be physiological, for example, as a result of iterative stimulation of the sympathetic system. Such metachronoses have recently been the chief study of Lapicque's disciples. This paper provoked Rushton to remind us that many workers (notably Keith Lucas) have failed to observe any metachronosis as a result of curarisation, and that one of the most certain ways of changing the apparent time relations of an excitable tissue is to change the size and disposition of the stimulating electrodes.

Representing the physiology of the circulation and respiration, we may instance the communications of Anrep and his co-workers (Cairo), who reported the results of their investigations on the respiratory variations in the heart frequency, using innervated heart-lung and similar preparations. They have come to the conclusion that these variations have both a central and a reflex origin, and their papers were followed by a discussion, which was all the more welcome in comparison with the apathy of the audience on most occasions, and in which Prof. Hering (Cologne) took a prominent part.

Among the more interesting contributions in the field of metabolism were three from R. A. Peters and his school (Oxford) on the nature of the function of vitamin B in nervous tissue. Different parts of the brains of pigeons were minced and incubated in phosphate buffer at *p*H 7·4, and the rate of oxygen consumption measured. In the absence of added substrate, or if the substrate were succinic acid, no significant difference could be observed between the oxygen consumption rate of the tissues of normal and of avitaminous birds. The ability of the tissue to oxidise added glucose was, however, markedly less in the case of avitaminous birds and the difference was even more apparent when lactate was the added substrate. The pathological tissue had in this case only 60–70 per cent of the respiration rate of the normal. Not all parts of the brain appeared to be affected: the optic lobes gave the most striking results, whilst cerebellar tissue seemed to be unaffected. That the effect is directly related to the vitamin deficiency and is not merely the result of a lowered vitality, was clearly demonstrated by the observation that within 24 hours of the administration of a curative dose of vitamin B_1 concentrate to birds showing serious polyneuritic symptoms, the tissues in question proved to be normal once more.

Of similar significance is the demonstration that the administration of the concentrate to the minced tissue *in vitro* abolishes at once the difference between the avitaminous and the normal tissue.

H. E. Himwich and others (New Haven) contributed the results of a careful study of alcohol metabolism in dogs and men. Clear evidence has been obtained of a state of acidosis during the twenty-four hours following the oral administration of ethyl alcohol equivalent in amount to eight 'double whiskies'. The bearing of this finding on the measurement of the respiratory quotients of human subjects needs no emphasis.

In the physiology of digestion, mention may be made of the accounts given by Soula and co-workers (Toulouse) on the relation between the blood sugar concentration and the secretion of the digestive juices, and of the studies on the effect of fat on gastric secretion and motility by Lim (Peiping) and Ivy and Zettelman (Chicago).

L. E. BAYLISS.
P. EGGLETON.

Co-operation in Electrical Standards

A FACTOR which has greatly facilitated the rapid development of the electrical industry throughout the world is the close agreement which exists in practically all countries as to the units in terms of which the various electrical quantities are measured. The international adoption of the units of current and voltage, for example, has been a great help to international trade. It is a pity that a similar simplification has not been introduced into the various national units of length, mass and money. Luckily, the agreement in electrical matters is based upon measurements of the highest precision made in the leading laboratories of the world. The close co-operation which exists between the scientific workers and standardising institutions of all nations has made this possible. A brochure recently published from the National Physical Laboratory (H.M. Stationery Office, 2s.), containing Papers 2 and 3 of its "Collected Researches", vol. 24, is an admirable illustration of this co-operation. Part 2 gives the intercomparison of the capacitance (capacity) and power factor of a mica capacitor (condenser). The tests were made by H. L. Curtis and C. Matilda Sparks of the Bureau of Standards and Dr. L. Hartshorn and N. F. Astbury of the National Physical Laboratory. Part 3 gives an international determination of the electromotive force of the normal Weston cell by P. Vigoureux of the National Physical Laboratory.

A mica condenser was transported on four occasions between the U.S. Bureau of Standards and the National Physical Laboratory. Seven sets of measurements were taken. During the first transportation a change occurred in the capacitance but no subsequent changes were observed. The change in capacitance of a mica condenser with barometric height is normally about 0·2 parts in ten thousand. The differences in the barometric pressure due to the relative altitudes of the two laboratories and ordinary atmospheric variations probably produced a change of less than one part in ten thousand. When due allowance was made, the measurements carried out in the two countries agreed to about the hundredth part of one per cent. This is quite satisfactory seeing that the methods of measurement adopted by the two laboratories were quite different.

Mr. Vigoureux's paper gives an account of new determinations of the international units of current and voltage which were made in Berlin in the summer of 1931 by members of the staffs of the National Physical Laboratory, the U.S. Bureau of Standards, Washington, and the Physikalisch-Technische Reichsanstalt, Germany. The measurements were made by weighing the amount of silver deposited when the current flows through a solution of silver nitrate. In the experiments described the same current was passed in succession through the apparatus belonging to the three national representatives, who each made weighings of the silver deposited. The mean results of a number of experiments agreed to about one five-hundredth part of one per cent. Standard cells used at the various laboratories as standards of voltage were measured in terms of the current so determined, and certain small discrepancies which had been suspected between measurements made in the different countries were accounted for satisfactorily.

Building Research*

MANY developments in the work of the Research Station near Watford are described in the Report of the year's work of the Building Research Board recently published, and in spite of necessary economies evidence of useful activities for the improvement of materials and construction are no less apparent than in former years.

The cost of building is influenced by the regulations enforced in connexion with construction, and the modification of these regulations so far as London is concerned has called upon the work of the Station. At the request of the London County Council, a committee has been set up to review the present methods and regulations for the use of reinforced concrete and a considerable part has been taken in the work of the Steel Structures Research Committee, resulting in revised regulations by the Council on the subject of steel-framed buildings which should appreciably assist the steel industry and help to reduce building costs.

Tests on building materials are naturally a large item in the list of the researches undertaken by the Station and the increasing number of requests for such tests from outside has made some definite policy on this matter imperative. It has been decided to enlist the services of approved firms of testing engineers and institutions in carrying out this work under the supervision of the Station rather than incur large capital outlay, and this effort to reduce overlapping and utilise existing agencies is to be commended. The tests thus made will be to the approval of the Station, which will issue certificates upon them.

* Department of Scientific and Industrial Research. Report of the Building Research Board, with the Report of the Director of Building Research, for the year 1931. Pp. ix+158. (London: H.M. Stationery Office, 1932). 3s. net.

The London County Council has approached the Building Research Station on the subject of fire risks, and the testing of materials for fire resistance, necessarily a matter involving considerable capital cost, is being debated with firms interested in the production of such materials. For experiments on the heating of buildings it is proposed to construct a special house where walls, floors and ceilings would be capable of thermal control, while for the prediction of sunlight obtainable by any room in a proposed house a simple instrument, the 'helidon', has been designed. The difficult problem of excluding damp from dwellings has been further investigated, and it would appear that a large number of specifics for treating walls to prevent the entrance of moisture are of very small value. Much remains to be done on this subject, but it seems likely that some means of allowing moisture to evaporate externally is more promising as a solution than attempts to render walls wholly impervious.

In connexion with the weathering of stones, the work of the Station on the selection of stone for repairs to the Houses of Parliament will be remembered, and now a survey of building stone resources is being undertaken in collaboration with H.M. Geological Survey, nearly 150 samples of Portland stone having been examined during the past year. The selection of suitable stone for building has, as is too well known from examples of decay, a very marked bearing on the ultimate cost of upkeep, and as this decay is due to many diverse agencies which operate very unequally in different localities, the acquisition of adequate knowledge requires prolonged investigation.

This survey by no means exhausts the account of the work done during the year by the Building Research Board, as indicated in the 150 pages of the Report, but is sufficient to show the contribution which the Research Station is making to bring the appreciation of the fruits of science home to the architect and industrialist and to indicate how such knowledge can be turned to practical account.

Physics in Meteorology

THE eighteenth lecture of the "Physics in Industry" series founded by the Institute of Physics was delivered on November 2 by Dr. G. C. Simpson, Director of the Meteorological Office, who took as his subject "Physics in Meteorology." Dr. Simpson said that meteorology is mainly applied physics; every branch of physics finds an application in it and he described five recent meteorological investigations which have respectively depended on an application of sound, light, heat, magnetism and electricity.

When large and violent explosions occurred it was noticed that the sound was loudest near the origin and then decreased, as one would expect, until at a certain distance, about sixty miles, it could no longer be heard. The surprising observation, however, was made that at still greater distances, more than 120 miles, the sound was again audible. After the War, much work was done to try to find an explanation of this curious effect. In Great Britain, Dr. F. J. W. Whipple of Kew Observatory organised an investigation and records were obtained at Sheffield, Birmingham, Bristol, Nottingham and Cardiff of the sounds made when large guns were fired in Shoeburyness, near the mouth of the Thames. The result of this work has shown that the old idea that the upper atmosphere—the stratosphere—is cold throughout, can no longer be held. The stratosphere is cold up to a height of about 25 miles and then it becomes warm again and at great heights becomes even warmer than at the surface.

The theory of optics has been used very much in meteorology especially to determine whether clouds are composed of water or ice, but recently spectroscopy has been used by Dr. G. M. B. Dobson, of Oxford, to investigate the amount of ozone present in the upper atmosphere. He finds that, while there is practically no ozone lower than 30 miles above the surface, at greater heights there is a relatively large quantity and it is the presence of this ozone which makes the upper atmosphere warm. A very unexpected result has come out of this work, for Dr. Dobson shows that the ozone is not uniformly distributed, but is concentrated in the neighbourhood of cyclonic depressions and is relatively weak in the neighbourhood of anticyclones. How cyclones and anticyclones, which are known to be phenomena of the lower atmosphere, can effect the amount of ozone 30 miles up in the atmosphere, or whether it is the other way about and the ozone causes the cyclones, are problems which cannot yet be solved.

For his example of the application of the physics of heat to meteorology, Dr. Simpson described some of his own work on the balance of incoming and outgoing radiation. Heat reaches the earth as short-wave radiation from the sun and leaves again as long-wave radiation from the upper atmosphere. The incoming radiation is much greater in equatorial than in polar regions, thus accounting for the difference of temperature between the equator and the poles. Calculations, however, show that the outgoing radiation is practically the same from all parts of the earth, and the poles send as much radiation into outer space as do the equatorial regions. As the polar regions send out much more heat than they receive from the sun, the loss has to be made up by transfer of heat from low to high latitudes. It is the transfer of this heat which is the driving force of the winds.

Magnetism has not much direct effect on the atmosphere and, therefore, does not enter much into meteorology: but in most countries the study of the natural magnetism of the earth—terrestrial magnetism—is part of the duty of meteorologists, and in Great Britain two of the chief observatories where terrestrial magnetism is studied are under the control of the Meteorological Office. Terrestrial magnetism is known to be greatly affected by the activity of the sun and so is the atmosphere, but it has always been difficult to find any relationship between terrestrial magnetism and the atmosphere. Recently, however, Mr. J. M. Stagg, who is at present in charge of the British Polar Year Expedition to Fort Rae in Canada, has found an interesting relationship at Aberdeen between magnetic activity and the barometric pressure. This relationship, however, must be examined further before it can be shown to be real.

Electricity, unlike magnetism, plays an important part in meteorology, especially in thunderstorms. Dr. Simpson, however, discussed another aspect of

atmospheric electricity and described the electrical field which always exists even in fine weather near the earth's surface. He said that this field is probably due to the fact that the conducting layers in the upper atmosphere, the so-called Kennelly-Heaviside and Appleton layers, are maintained at a potential of several million volts above ground potential. How the difference of potential is maintained is one of the main problems of atmospheric electricity. Prof. C. T. R. Wilson considers that thunderstorms are the cause, while others consider that some solar effect is responsible because the potential is highest each day when the earth's north magnetic pole points most directly towards the sun. In conclusion, Dr. Simpson described some recent experiments at Kew Observatory which indicate that the ionisation of the lower atmosphere is not uniform, but that the ions occur in parcels. This observation is likely to have an important bearing on the theory of the ionisation of the atmosphere.

University and Educational Intelligence

BRISTOL.—Mr. N. F. Mott, lecturer in mathematics in the University of Cambridge, has been elected to the Melville Wills chair of theoretical physics in the University of Bristol in succession to Prof. J. E. Lennard-Jones. By agreement with the University of Cambridge, Prof. Lennard-Jones will give assistance to the Wills Laboratory during the present session and Mr. Mott will not take up his duties until next autumn.

Dr. C. M. Yonge, of the Marine Biological Laboratory, Plymouth, has been appointed to the chair of zoology in the University.

CAMBRIDGE.—Dr. Drury has been appointed Huddersfield lecturer in special pathology. J. S. Turner, of Selwyn College, has been appointed to the Frank Smart University studentship in botany.

Sir James Jeans will deliver the Henry Sidgwick memorial lecture on November 26 at 5 P.M. in the College Hall, Newnham College. The subject of the lecture is "The Furthest Depths of Space".

LONDON.—In consequence of the announcement that Major the Hon. John J. Astor, M.P., was the anonymous donor in 1920 of the gift of £20,000 for the endowment of the University chair of physiology at the Middlesex Hospital Medical School, it has been decided that the title of this chair shall now be the "John Astor Chair of Physiology tenable at the Middlesex Hospital Medical School". As recently announced, a gift of £1,500 a year for seven years has been promised by the Prudential Assurance Company for the endowment of the chair of public health tenable at the London School of Hygiene and Tropical Medicine; it has been decided that the chair shall be known as the "Prudential Chair of Public Health" for the duration of the gift.

The title of emeritus professor of mathematics in the University has been conferred on Prof. S. A. F. White, on his retirement from the chair of mathematics at King's College.

MANCHESTER.—Dr. John Hollingworth has been appointed to succeed Prof. Miles Walker, who has held the chair of electrical engineering in the University and College of Technology since 1912. Prof. Miles Walker's many services to electrical engineering are well known; in Manchester he will be remembered for the close association of the engineering industry and the University which he has been instrumental in bringing about. Dr. Hollingworth was educated at Bradfield College, University College (London), Peterhouse (Cambridge) and the City and Guilds Engineering College. He was a wrangler at Cambridge in 1907, and has since held various appointments both industrial and academic. Prior to 1917 his experience was all in heavy engineering; since that date he has been engaged in radio research.

The following appointments have also been made: Demonstrator in anatomy, Mr. A. N. Birkett; demonstrators in pharmaceutics, Dr. Kenneth Bullock and Mr. S. L. Prescott; lecturer in mathematics (College of Technology), Mr. James Topping; assistant lecturer in metallurgy and assaying (College of Technology), Mr. E. A. Fowler; demonstrator in physics (College of Technology), Mr. Joseph Bor.

Mr. C. J. P. D. La Touche has resigned his post as research assistant in mycology on his appointment as lecturer in botany in University College, Dublin.

The Council has accepted from Mrs. R. W. Williamson a portrait in oils of her father-in-law, the late Prof. W. C. Williamson, who was in charge of the teaching of zoology, botany and geology in Owens College from 1851 until 1892.

THE thirty-third annual meeting of the Science Masters' Association will be held at the University of Bristol on January 3–6, 1933, under the presidency of Prof. A. M. Tyndall, who will deliver an address on "Gaseous Ions". Several lectures have also been arranged to be given by members of the staff of the University. Further information can be obtained from the Annual Meeting Secretary, Shirley Hill, Boden Road, Hall Green, Birmingham.

Calendar of Geographical Exploration

Nov. 8, 1903.—An Antarctic Rescue

Capt. Irizar rescued Otto Nordenskiöld and his party. Dr. O. Nordenskiöld, nephew of the hero of the *Vega* expedition, with C. A. Larsen and J. Gunnar Andersson, left Göteborg on October 16, 1901, for research work in the antarctic. His vessel was off the South Shetlands in 1902 and proceeded down the west coast of Louis Philippe Land, discovering that the Orleans channel did not reach Weddell Sea, but was merely a part of Gerlache Strait. On February 12 Nordenskiöld, three scientific workers and two sailors, landed on Snow Hill Island in 64° 25′ S. and established winter quarters. The ship went north to carry on researches in the open sea. She did not return in spring as expected and the party was compelled to spend a second winter, during which the insularity of Ross Island was established. In October, 1903, Nordenskiöld encountered Andersson and a companion, black from head to foot and with long black hair and bushy beards, so that they were at first not recognisable. They had left the ship when it became clear that she could not reach the winter camp and had set out on foot, eking out their scanty diet with seal oil. On November 8, Capt. Irizar of the Argentine naval vessel, *Uruguay*, reached Snow Hill Island and, that night, by an extraordinary coincidence, Larsen and the crew also arrived. The ship had been caught in the ice in Erebus and Terror Gulf in January and so

damaged that she sank; the crew had wintered on Paulet Island. Capt. Irizar's timely arrival thus saved the whole party.

Nov. 10, 1898.—Sir Charles Hose in Sarawak

Sir Charles Hose, with Drs. McDougall and C. S. Myers, set out for the hitherto unexplored regions between the headwaters of the Batang-Kayan, Rijang and Baram Rivers in the Madang territory of Borneo. Between 1884 and 1892, Hose explored most of northern Sarawak and opened up much previously unvisited country in the valley of the Baram River.

Nov. 12, 1799.—Alexander von Humboldt

On the night of November 12–13, Alexander von Humboldt observed in Cumana, Venezuela, that meteor shower which forms the starting point of our knowledge of the periodicity of the phenomenon. Humboldt and A. Bonpland, the botanist, had sailed from Corunna in 1799, stopped at Teneriffe and ascended the peak, and thence proceeded to Cumana. From Cumana they went to Caracas and in 1800 Humboldt left that town to explore the Orinoco River. He covered 1725 miles of wild and uninhabited country and confirmed the fact that the Cassiquiari links the Amazon to the Orinoco. Teixeira had been told of the probability of this when he explored the Amazon in 1637–39, but the statement was received with incredulity. On November 24, 1800, Humboldt and Bonpland went to Cuba and, after a stay of some months, recrossed to Cartagena. They ascended the Magdalena, crossed the Cordilleras and reached Quito on January 6, 1802. They climbed Pichincha and Chimborazo and made an expedition to the sources of the Amazon. At Callao, Humboldt observed the transit of Mercury. Humboldt contributed much to the purely exploratory side of geography, but his more important work was the laying of the foundation of the broad outlines of physical geography and meteorology. He discovered the decrease in intensity of the earth's magnetic force towards the equator; he worked out a formula relating decrease in temperature to elevation above sea level; he introduced the idea of isothermal lines. He was also interested in the relation between plant and animal life and its environment. Humboldt's example was a powerful stimulus to the development of the scientific side of subsequent explorations.

Nov. 12, 1882.—Kishen Singh's Famous Journey

"A–K", Kishen Singh, arrived at Darjeeling after the last and most remarkable of his memorable explorations. He set out from Darjeeling in 1878, reached Lhasa, travelled across Tibet, crossed the Altyn Tagh and reached Sa-Chow, his northern limit. He then crossed eastern Tibet, entered China and journeyed through Batang. He could not get a passage to Assam, so he turned northwards and made a great bend round the Brahmaputra River, which he ultimately touched at Tsetang. This magnificent feat included the crossing of a vast area of entirely unknown country, from which he brought back details of atmospheric conditions, population and trade possibilities. His survey suggested the belief, confirmed later by the travels of Kinthup, a native of Sikkim, that the Brahmaputra, the Dihang and the Tsang-po were all one river. In a previous journey in 1871, Kishen Singh had solved the geography of the region between Shigatse and the great lake Tengri Nor, north of Lhasa, and had thoroughly explored a northern tributary of the Brahmaputra.

Societies and Academies

CAPE TOWN

Royal Society of South Africa, Aug. 17.—E. Newbery: Electrolytic rectifiers. The theory that the behaviour of a valve electrode can be accounted for by assuming the formation of a semi-permeable membrane on the surface is fully justified by further investigation with the aid of the cathode ray oscillograph. A valve electrode is capable of rectifying an alternating current only when the anodic membrane is not reducible by atomic hydrogen, and further, in the case of aluminium, the membrane consists of the oxide only and not the hydroxide.—G. M. Dreosti: A method of measuring the pressures on oranges *during and after the process of packing*. The pressure upon an orange has been found to vary with the details of packing. A few measurements of the change of pressure with time in a cold store indicate that the pressure falls roughly 0·35 per cent an hour during the first hundred hours. Making a few assumptions, simple formulæ have been set up for the derivation of the forces between two oranges in contact and between an orange and the faces of the box with which it is in contact.—F. G. Cawston: Native medicines in Natal. An account is given of investigations into South African native and Indian herbal remedies used and sold in Natal for medical purposes.—Sir Thomas Muir: Note on a set of equivalent determinants connected with a 3-by-6 array.—I. Schrire and H. Zwarenstein: Protein metabolism and the effects of injection of testicular extracts on castrated animals. It has previously been shown that after castration there is a marked increase in creatinine excretion in male rabbits. Following the injection of testicular extracts into castrated animals, there is a drop in the high creatinine excretion to pre-castration levels. This drop is only transient, and in a day or two after the injection, the creatinine excretion is once more at the normal castration level.

ROME

Royal National Academy of the Lincei, May 15.—V. Nobile: Laws of central force corresponding with fixed trajectories, and a noteworthy particular case. The problem considered, which is a particular case of that stated and resolved by Sakellariou (1929), is as follows: Given a family of curves by means of a polar equation containing k parameters, $f(r,\theta : a_1 a_2 \ldots a_k) = 0$, to determine the most general law of central force (with intensity a function of the point and vector velocity) with which the given lines correspond as trajectories.—A. Sommerfeld: Asymptotic integration of the Thomas-Fermi differential equation.—Giacinta Andruetto: The Saint-Venant formulæ for the varieties V_n with constant curvature. The simple procedure recently given for obtaining the Saint-Venant formulæ for any variety with three dimensions is now extended to the case of a variety V_n with n dimensions, supposing a constant Riemannian curvature.—A de Mira Fernandes: The unitary theory of physical space.—A. Kolmogoroff: The general form of a homogeneous 'stocastic' process (a problem of Bruno de Finetti).—B. Manià: A theorem of existence in the calculus of variations.—M. L. Dubreil-Jacotin: Waves of permanent type in heterogeneous liquids. Various rigorous properties of these waves are established for the case in which the movement is the same in parallel vertical planes,

so that it may be studied in one of these planes as a two-dimensional movement.—Z. Pycha: Relativity in the microcosm.—A. Desio: Presence of the Eocene in Eastern Fezzan (Tripoli).—Silvia Colla: Investigations on the movement of the stamens in certain Berberidaceæ. Action of multiple subliminal stimuli of low frequency.—Z. Danin: Investigations on the gaseous content of certain Algæ. The gases contained in *Enteromorpha compressa* Ag.

SYDNEY

Linnean Society of New South Wales, July 27.—C. Deane: Trichopterygidæ of Australia and adjacent islands. Descriptions of two new genera and eighteen new species. A key to genera dealt with by the author in this and the two previous papers is also given with a table showing the numbers of known species from various parts of the world.—F. A. Craft: The physiography of the Shoalhaven River valley. (5) The upper valley and the stream system. Two peneplain levels are recognised towards the head of the Shoalhaven—one of a composite nature with its principal development between 2400 ft. and 2600 ft., in which was developed the Shoalhaven Plain farther to the north at a slightly lower level, and an older feature which rises from 3000 ft. in the middle valley to 4000 ft. at the head of the river. The stream system appears to have developed on this older surface, although some variation has taken place as a result of limited captures by streams cutting back from the south-east along lines of weakness.—A. Burges: Notes on the mosses of New South Wales. (1) Additional records and description of a new species of *Buxbaumia*. This is the first paper of a series intended to bring up to date the census of New South Wales mosses published by Watts and Whitelegge in 1902 and 1905. A list is given of records in the subclass Bryales, order group Eubryinales, and a new species of *Buxbaumia* is described from the Williams River, N.S.W.—G. A. Waterhouse: Australian Hesperiidae. (2) Notes and descriptions of new forms. Two new species and fifteen new subspecies are described. In addition, one new species is recorded from Australia for the first time. It is shown that in the Australian region many of the genera of the subfamily Pamphilinæ have pairs of closely related species. Notes are given on a number of subspecies, showing their relationship to the typical species found in the oriental region.

Aug. 31.—J. R. Malloch: Notes on Australian Diptera (32). Three new species are described and a key is given for the species of the genus *Fergusonina*, family Agromyzidæ. A new genus and species of the family Ochthiphilidæ are also described. All the species described as new are probably of economic importance.—F. A. Craft: The physiography of the Shoalhaven River valley. (6) Conclusion. The master peneplanation recorded in the area preceded the deposition of the Permian Upper Marine series, and later gentle uplift at intervals has allowed the invasion of the elevated plateau mass by streams, which have carved a series of terraces on a large scale, finally giving the incomplete peneplain which comprises a great part of the area, and has extensive deposits of Tertiary drift and basalt on its surface. The original divides were aligned east and west, and streams flowed from them to ancient depressions; there was a tendency towards capture from the eastern coast as the various uplifts took place.—F. A. Craft: Notes on erosional processes and stream gravels. Negative forms in granite areas are correlated with well-developed stream systems. The widening of valleys in the horizontal rocks of the Blue Mountain plateau are dealt with; the conditions of formation of ellipsoidal and flattened stream gravels in terms of stream power and motion and the climate indicated by Tertiary drifts of the Shoalhaven Valley are described.—A. Jefferis Turner: Revision of Australian Lepidoptera. Oecophoridæ (1). A key is given for indentification of the twenty-four genera. This part deals with sixteen genera, and includes descriptions of three genera and thirty species as new.

Forthcoming Events

MONDAY, Nov. 7

NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY—(at the London School of Economics and Political Science).—Dr. George H. Miles: "The Human Factor in the Marketing and Distribution of Goods", at 6 P.M. (succeeding lectures on Nov. 14 and 21).

ROYAL INSTITUTE OF BRITISH ARCHITECTS—(Inaugural Meeting).—Presidential Address, at 9 P.M.

TUESDAY, Nov. 8

KING'S COLLEGE, LONDON.—F. H. Preece: "Boiler House Economics", at 5.30 P.M.

ILLUMINATING ENGINEERING SOCIETY—(at the Laboratories of the General Electric Co., Ltd., Wembley).—C. C. Paterson: "Luminous Discharge Tube Lighting", at 7 P.M.

ROYAL ANTHROPOLOGICAL INSTITUTE—(at the School of Hygiene and Tropical Medicine, Keppel Street, W.C.1).—Maj. P. H. G. Powell-Cotton: "Benin Brass Casting and Handicrafts in the Cameroons", at 8.30 P.M.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—C. H. Hampshire: "The British Pharmacopœia, 1932", at 8.30 P.M.

ROYAL INSTITUTION.—Prof. E. N. da C. Andrade: "Rays and Radiations", at 5.15 P.M. (succeeding lectures on Nov. 15 and 22).

WEDNESDAY, Nov. 9

ROYAL SOCIETY OF ARTS.—T. Thorne Baker: "New Developments in Colour Cinematography", at 8 P.M.

THURSDAY, Nov. 10

KING'S COLLEGE, LONDON.—Dr. J. A. Hewitt: "The Influence of Ductless Glands on Metabolism", at 5 P.M. (succeeding lectures on Nov. 17, 24 and Dec. 1).

Official Publications Received

GREAT BRITAIN AND IRELAND

The Scientific Proceedings of the Royal Dublin Society. Vol. 20 (N.S.), Nos. 21-27: Report of the Irish Radium Committee for the Year 1931 (including Reports by Oliver Chance, John A. Geraghty, Oswald J. Murphy, C. Factors of Industrial Development*

AMONG the duties charged on the Economic Advisory Council is that of considering the possibilities of new industrial development and particularly the measures which could be taken to foster the growth of new industries, whether they arise as the result of the application of the creative discoveries of modern science or not. The growing burden of the unemployment problem and the seriousness of the general economic position has induced the Council to pay particular attention to the relation of research to industrial development. It is at last being realised that industrial research is an important factor in the unemployment situation, and one that tends to create employment or at least to compensate for the displacement of employment in other fields as a result of increased mechanical efficiency or other changes.

It is probable that we have reached the end of an era in which the creative discoveries of science as applied in the electrical industries, automobiles, radio and the cinema, have found employment for millions and absorbed in productive work a large proportion of the increasing population of the world for whom under the old conditions no work could have been found. The advent of power production has already closed that era and brought new problems, the solution of which so far has eluded mankind. In the new era, scientific and industrial research are of equal importance as assisting to develop that flexibility which is essential if modern industry is to deal with problems of the magnitude of that of unemployment; and in equipping the nation to deal with the dislocation and reorganisation inseparable from the dynamics of industry or society.

In March 1931 the Economic Advisory Council appointed a Committee to consider broadly the position of industrial research in Great Britain, and in particular whether the proposal to establish a new central national research organisation would facilitate the promotion of industrial development as a means of providing additional employment. The report of this Committee gives a valuable survey of the existing organisation of industrial research in Great Britain with the definite object of discovering any overlapping which could be prevented by further co-ordination, or any gaps which should be filled either by

* Economic Advisory Council. Report of the Committee on New Industrial Development. Pp. 29. (London: H.M. Stationery Office, 1932.) 6*d*. net.

the development of existing organisations or by the creation of some new body, as was urged by Mr. A. P. M. Fleming in a paper before the Department of Industrial Co-operation at the British Association centenary meetings last year.

The major part of the survey of existing resources is devoted to a critical review of the Department of Scientific and Industrial Research and its research establishments, including the research associations, and the report places the responsibility for much of the prestige of this young Department on the exceptional combination of scientific attainments, administrative ability, zeal, persuasiveness and sympathetic understanding of the point of view of business possessed by those at the head of its staff. This is a tribute worth noting in view of a common tendency particularly in official circles to deny the possibility or existence of such combination of scientific attainment and administrative ability. With regard to the permanent institutions of the Department, the Committee comments on the absence from the National Physical Laboratory of any dubious schemes designed purely to be impressive, and it considers that the Laboratory has developed as an organic structure in response to clearly defined needs and purposes. Similarly such primary needs of the community as food, fuel, water-supply and buildings appear to be adequately covered by the other research establishments of the Department, and the work carried out by the Bridge Stress Research Committee, the Steel Structures Research Committee and the Locomotive Experimental Station Inquiry Committee is regarded as evidence of the ability of the Department to improvise a temporary special organisation to meet the need for special scientific investigation in any field of industry.

Commenting on the Research Associations scheme, the Committee points out that the Advisory Council which adopted the scheme deliberately rejected the idea of forming one central institution to which industries could turn for assistance in research, and suggests that experience has confirmed the view that a research association which a particular industry controls, for which it feels responsible and in which it takes a pride, is able to contribute to the development of mutual understanding between men of science and industrialists in a way that would not be open to a central institution. Moreover, the Research Associations have made discoveries of financial importance and have to a remarkable extent converted the British manufacturer from an attitude of scepticism to one of appreciation of the potentialities of scientific research. They have also established special departments for development work designed to assist in testing the results of their investigations on a practical scale, and it is clear that the Committee has formed a very high opinion of the merits of the Research Associations scheme.

Without detracting from the praise deservedly extended to many of these Associations, it is possible to feel that the Committee on Industrial Development is a little unduly optimistic about both their achievements and future prospects. Few of the Associations are self-supporting, and in fewer still has there been any sign that the industry as a whole is prepared to shoulder the full burden of financial responsibility of its research needs. In consequence, there is uncertainty about the continuance of the Associations, and the initiation of large scale development work is a much less simple problem than that confronting the research departments of large units of progressive industry, such as the General Electric Co., Metropolitan-Vickers, and Imperial Chemical Industries.

The Committee is accordingly unconvinced that an important gap exists in our existing arrangements for industrial research, which would be filled by the creation of a new national research organisation to draw up programmes of research into the application in industry of ideas, inventions, or processes at present undeveloped and likely to remain undeveloped, and to institute the necessary researches. While admitting that notably in the older industries, much research which might usefully be pursued is at present left undone, the Committee suggests that the need would be met by the Department of Scientific and Industrial Research establishing a branch for the purpose of initiating the stimulation of research in such industries, and directs attention to the readiness of the Department to create organisations of its own in important industrial fields where it recognises the existence of a need for research.

The proposal for the creation of a new central research organisation rests on a distinction drawn by its supporters between research directed to the improvement of existing industries and that directed to the creation of new industries, the latter being normally responsible for increasing employment. While it is undoubtedly true that the application of scientific discoveries resulting

in the creation of new industries has given employment to millions, under modern conditions the displacement effects are becoming more serious, so that rise of a new industry frequently means the contraction of an older established one. So far as employment is concerned, the national importance of scientific research as a factor in determining the rise of new industries lies rather in the consequent ability of the nation to minister to the new needs, thus giving employment to some or all of those inevitably displaced by the disappearance of needs to which the older industries ministered. In the minds of certain leaders of industry, such as Sir Harry McGowan, to judge from his presidential address last year to the Society of Chemical Industry, there are even doubts whether violent fluctuations caused in industry by, among other factors, the sudden exploitation of a scientific discovery, are really beneficial; and in the type of planning towards which the world is tending, provision for fundamental research and the deliberate exploitation of its results either by the State or by industry seems essential.

Apart from this factor, it is at least open to doubt whether the distinction drawn between the two types of research is valid and whether scientific research can be directed specifically to the creation of new industries. We are still without a real technique of discovery, and important industrial developments as often as not are based on purely fortuitous discoveries. In general, the fundamental discoveries have resulted from patient and disinterested investigations, the quest of truth for its own sake. Where scientific research has produced striking results from its direct application to industrial purposes we have entirely different conditions: a mass attack by a team of specialists on a clearly defined objective in a field where a considerable body of accumulated knowledge already exists.

The Committee refers to the work of the Fuel Research Board on the economical extraction of oil from coal as an example of the ability of the Department of Scientific and Industrial Research to take the initiative in problems of this type as they arise, and accordingly it considers that here again the proposed new body would be likely in practice, by confusing purposes and distracting effort, to injure rather than forward the cause of scientific research in industry. Even in regard to large scale tests the requirements of development research appear to be sufficiently covered by the machinery of the Department of Scientific and Industrial Research, although the Committee recommends that it is desirable that there should be at the disposal of the Government a small fund capable of being readily used for research developments, and that provision should continue to be made in the Department's annual estimates for such a sum for expenditure on research developments or unforeseen requirements.

The report of the Committee makes a convincing case for the adequacy of the existing Government organisation for the promotion of industrial research, which may be readily accepted without suggesting that the position is entirely satisfactory. The real trouble is that indicated in the last annual report of the Department. While the existing organisation is adequate and sufficiently flexible to meet the varied needs, there is not yet a sufficient general acceptance in industry of the fundamental importance of research as a fixed charge comparable with obsolescence, insurance, etc., and an essential factor in progress. The work of the Department is limited by the extent to which a scientific outlook prevails in industry, and the real task is one of educating industry to use the facilities already available rather than to create a new organisation with ill-defined objectives and probable overlapping with the functions of existing organisations. It is only as this task of education, both in industry and in public affairs, is tackled with real energy and efficiency that we can hope to close those gaps which exist in our national organisation of research or secure the full utilisation of the facilities already available.

Despite the fact that new industries are not in general created by direct scientific discoveries, long range fundamental research is of prime importance to the nation, and at the present time the declared policy of the Committee of the Privy Council to concentrate available funds on the work of the most immediate practical value to industry tends to create a dangerous gap. It is the long range type of research that is most liable to be neglected by industry, and the present report has little to say on the manner in which the task of education is to be undertaken or the serious danger the situation represents to posterity. Admittedly the available facilities are not yet being fully utilised, and the stability of certain features of the national organisation such as the Research Associations is uncertain. We cannot, for example, regard the position as satisfactory

when an industry representing £500,000,000 of invested capital has difficulty in providing the sum of £21,000 required to maintain a Government grant of £5,000 to its research association, and this in spite of the successful conclusion of researches on insulating oils and buried cables which at an aggregate cost of about £27,000 have resulted in total savings to the industry of at least £300,000 a year as well as adding something like £4,000,000 to the value of the existing cables.

Important sections of industry still notoriously owe their difficulties less to economic conditions than to the past neglect of scientific methods and research. The Report of the Committee on New Industrial Development underlines once more the necessity for a more widespread and intensive educational campaign to demonstrate both the capacity of scientific research to provide, not the ready-made solution of industrial difficulties but the technique of solution, and the ability of the scientific worker to co-operate in the conduct not merely of the investigations themselves but also of those administrative problems involving scientific and technical factors which abound everywhere in industry and the State to-day. It is only as a result of such an educational effort that we can expect to find alike in industry and in the State a scientific outlook in high places which will make possible the statesmanlike planning and utilisation of our full resources, whether of the Department of Scientific and Industrial Research, of industry or of the universities, and the prosecution of industrial and scientific research in all its varied phases from the fundamental or long range scientific research to the semi-technical scale in a measure commensurate with national needs.

Himalayan Exploration

The Italian Expedition to the Himalaya, Karakoram and Eastern Turkestan (1913–1914). By Filippo De Filippi. With Chapters by G. Dainelli and J. A. Spranger. Pp. xvi+528+20 plates. (London: Edward Arnold and Co., 1932.) 50*s*. net.

WE expect this production will rank as one of the most elaborate books of travel published, both as regards letterpress and the three hundred illustrations, not to mention maps and mountain panoramas. It is indeed worthy of such a leader as Cav. Filippo De Filippi, so well known as a traveller and explorer in the Himalayas, which he first visited as a member of H.R.H. the Duke of the Abruzzi's celebrated expedition to the Baltoro glacier in 1909, of which the author was also the chronicler.

The expedition occupied from August 1913 until December 1914. It was originally described in the Italian edition published in 1923 of which this is mainly a translation, but has been treated by the author as a new and revised edition. This has given him an opportunity of referring to expeditions which have taken place since the original was issued. He has also added a general chapter on the scientific results which have been only partly published in detail up to date. Two additional chapters have also been added by Prof. Giotto Dainelli and Mr. J. A. Spranger. The author remarks in the preface: "I do not know if any other trans-continental expedition has ever been organised through such difficult regions, crossing vast desert tracts devoid of sustenance for man and beast; with so extensive and complex a programme of scientific research, requiring not only a considerable company of trained workers but also very cumbersome equipment, including quantities of the most delicate instruments, which had to be transported with infinite precautions and needed unremitting care and supervision." This quotation will give some idea of what had to be accomplished over, perhaps, the most difficult country in the world.

The expedition was essentially a scientific one, and had for its object investigations into geology, glaciology and morphology, anthropology, meteorology, and, above all, the author was interested in gravimetric measurements and the deviation of the plumb-line with the view of investigating conditions of isostasy "when expertly carried out in the heart of the Himalayas and Karakoram, where great altitude and various practical difficulties had combined, up till now, to prevent the making of such delicate observations." A further object was to make systematic observations for terrestrial magnetism, and finally, the exploration and mapping of the eastern end of the Karakoram and its unknown glaciers.

It was certainly an ambitious programme, which so far as we know, was efficiently carried out, though the detailed scientific accounts are not yet completed. Cav. De Filippi took with him a carefully selected band of Italian experts with Commander (now Admiral) Prof. Alberto Alessio, as second in command. Col. Henry Wood, R.E., of the Survey of India and Mr.

John Spranger were the two English members. In all there were eleven Europeans, each an expert in his own line, and two Indian surveyors, Rai Sahib Jumna Prasad and Rai Sahib Shib Lal, lent by the Government of India.

The volume before us is mainly descriptive of the journey, localities and their people, passed through from the plains of India to the heart of the Himalayas, and we fancy little has escaped the notice of this observant traveller. Local interest has been added by a sketch of the history and religions of these remote parts. In search of information every available source has been used. Numerous notes and references are scattered throughout the pages.

After passing from India through Kashmir, taking geodetic and geophysical observations at various places on the way, the expedition reached Skardu, the capital of Baltistan. There they spent the winter of 1913–14; established observing stations and settled down to a regular series of observations, while Prof. G. Dainelli made geological excursions in the province of Baltistan, at the same time examining the social and economic condition of the people he came across. Perhaps in no part of the world is a larger proportion of the inhabitants dedicated to the service of religion; this subject, therefore, naturally occupies much attention.

In the spring of 1914 the expedition moved up the Indus to Leh, the capital of Ladak, "a true little capital, the seat of a tiny cosmopolitan world with various classes and categories of citizens." Here headquarters were established for 2½ months. The time was occupied with geophysical, meteorological and magnetic observations and excursions in the neighbourhood, by which Prof. Dainelli continued his researches, a description of which he contributes in two chapters. In the middle of May 1914 the whole expedition left Leh for the Eastern Karakoram, crossing by the Lhang-la into the Shayok valley *en route* for the Depsang Plateau where, on June 1, a base camp was formed at a height of 17,590 ft. above sea level from which to work the summer campaign of exploration and for the setting up of an observing station.

It was from here the main exploring work was undertaken; the survey of Rimu glacier and of the upper waters of the Shayok and Yarkand rivers being the chief objective. Other trips connected with geological research were also undertaken. Although the Rimu glacier had often been seen before, this is, we believe, the first time it was thoroughly explored and mapped. It forms a peculiar feature in that the continental water divide between Central Asia and India actually crosses this immense glacier; the waters from one branch flow into the Shayok river and thence to the Indus, and from another branch to the Yarkand river, which is eventually absorbed in the Tarim basin of Central Asia. Four chapters are devoted to the exploration of this area and to the discussion of the various topographical problems of this complicated jumble of mountains and glaciers.

In the final chapter a synopsis of results is given. Observations for deviation from the vertical and anomalies of gravity were taken at a series of fourteen stations beginning at Dehra Dun in India and ending at Tashkent in Central Asia, most of these being at a great height above mean sea level. Relative gravity was determined by Sterneck's modified apparatus, eight pendulums being used. For the determination of the deviation of the plumb-line, where it is necessary to make a comparison between astronomical and geodetic co-ordinates, the zenith telescope and transit instrument were used. Difference of longitude was determined by wireless signals specially transmitted from Lahore and timed for the expedition at Dehra Dun. By this means it was possible to obtain a more accurate value of the astronomical longitude than could have been done before the days of wireless.

These observations have an important bearing on questions of isostasy, which have occupied the attention of Indian geodesists since the time of Everest. We have not, however, had an opportunity of seeing the results, though it is stated the observations "confirm the general conclusions drawn by the Survey of India from their own, taken in connection with those of the Russian geodetic service: namely, that gravity values are generally in excess in the Himalayas and Karakoram ranges, and in defect to the south and north of them, pointing to equal conditions of compensation, or of lack of compensation, in the Indo-Gangetic plain and the plain of Turkestan." A complete set of magnetic observations was also made at each station. The topographical work, carried out by Col. Wood and Mr. Spranger and the Indian surveyors Jumna Prasad and Shib Lal, has been embodied in a map on a scale of 1/250,000, which is with the book.

A full set of meteorological observations was

taken and pilot balloon ascents were made: "these have resulted in a large quantity of new data."

As of interest in the realm of geology, it is stated, "contrary to the current view that this group of mountain ranges has not been subject to great glacial expansions in the Quaternary Age, Dainelli has found the occurrence of two great expansions, and of at least four minor ones." "Particularly interesting is the demonstration of two periods of uplifting which took place in the Quaternary; one affecting also a large portion of the Trans-Himalayan region, the other only the chain of the Himalaya (Pir Panjal). These uplifts have a general bearing on the question of the glacial period." The geological investigations made, and the specimens collected, by the members of the expedition should add much information about this region.

It is stated that there will be, when complete, ten volumes of scientific results from the expedition. As a book of reference and a guide to future explorers the volume before us is invaluable; it is, of course, impossible in a short review to do justice to it. There will soon be little left that has not been explored and mapped in that area generally known as the Karakoram. A good deal has been done since the De Filippi expedition.

We think the maps accompanying the volume might with advantage have had more of the names mentioned in the text inserted on them, without any overcrowding; it would have made the text easier and quicker to follow. The volume contains an extensive bibliographical index and the translation has been well done by Mr. H. T. Lowe-Porter.

H. L. CROSTHWAIT.

Social Anthropology in Epitome

Early Beliefs and their Social Influence. By Prof. Edward Westermarck. Pp. vi+182. (London: Macmillan and Co., Ltd., 1932.) 7*s.* 6*d.* net.

IT is not given to every anthropologist to be pre-eminent alike in the field and in the study; and it is only when this happy combination of interests occurs that facts and ideas are likely to be brought into harmonious relation. Prof. Westermarck actually started his career as a theorist, obtaining as a comparatively young man the most brilliant success with his "History of Marriage"—a work which later he crowned, if it was scarcely possible to surpass, with his admirably documented treatise on "Comparative Morals". On the other hand, he has given many of his best years to first-hand study of the social institutions of Morocco, where so many grades of culture exist in juxtaposition that a stratigraphy covering all the transitional phases between savagery and civilisation will reward research, given wide enough acquaintance with the conditions and the requisite analytical acumen. Thus it is fitting that, in the ripeness of his knowledge and experience, such a thinker should set himself to give summary expression to his more general convictions concerning methods and results.

Those familiar with Prof. Westermarck's books —and they will amount to most serious students of anthropology—will perhaps find here no fresh surprise sprung upon them, but on the other hand will be glad to have the principles on which he has come to rely formulated and defended with such masterly clearness. Thus it is well known that Prof. Westermarck has always sought to steer a middle course between Frazer's and Durkheim's attempts to differentiate magic from religion. He agrees with the one that they severally imply coercion and conciliation; but with the other that both alike relate to the supernatural, and therefore have more in common than Frazer's notion of magic as "the bastard sister of science" would make it possible to assume. But this compromise involves difficulties of its own. Thus he writes: "It has only reference to religion in the abstract, not to the various religions. In the popular sense of the word, which certainly must be respected, *a* religion may include many practices which are what I have called magical"; and he goes on to hint that the Christian use of holy water and even the Eucharist itself have a magical import. But surely, to deny a religious character to the central mystery of the typical religion of civilisation is simply to play with words, unless indeed a valuation is intended such as would be quite out of place in a purely scientific account of an evolutionary process.

Further, believing as he does that religion is born of fear and originates in emotions excited by contact with the uncanny, Prof. Westermarck is disposed to minimise its influence as a social force; so that one cannot but suspect him of conceiving it too abstractly, and therefore failing to do justice to its nature as a living and working

institution. When he says that the importance of the religious bond as apart from the influence of marriage, local proximity and a common descent has been slight in its bearing on the growth of social organisation, or when, again, he insists that "the moral influence of religion has often been greatly exaggerated", he seems to me to be eviscerating human history in the interests of a bloodless category. Thus I suppose that he would not deny the social and moral activities of the Christian Church, but would nevertheless declare the religious element in them to be but slightly responsible for the concrete results.

Obviously, if one starts from a primitive impulse so limited by definition that it can never alter by way of expansion or sublimation, then any progress that occurs in a complex with which it is connected must be due to something else. If, however, one plays fair all round and treats the remaining impulses concerned in similar fashion, thereupon it becomes quite impossible to account for any development at all. In fact it puzzles me altogether how 'religion' can be anything different in essence from *a* religion, since I take it to be rather the *formule d'ensemble* that covers any and every religion as such, however variously it may have evolved.

Meanwhile, whether the reader is always in sympathy with the point of view or not, he is sure to derive profit from the masterly grip on the relevant evidence which is displayed in the treatment of every special topic alike. One feels that half a century of study and experience is behind the elucidation of that many-sided theme, the relation of the sexes, together with the resolution of the paradox that primitive religion sets a value both on chastity and on unchastity in different contexts. Again, many side-lights are here thrown on the history of morals, as for example in relation to the duties of charity and hospitality towards men and of respectful behaviour towards gods. Moreover, with morality, law is so closely bound up that the part played by methods of procedure such as the oath or the ordeal in the administration of justice is duly considered in turn. Thus we have here in compact and lucid shape the mature reflections of one whose command of fact and independence of mind entitle him to rank among the foremost exponents of anthropology in all that variety of aspects constituting its social side.

R. R. MARETT.

Implications of Science

The Universe of Science. By Prof. H. Levy. Pp. xiii + 224. (London: Watts and Co., 1932.) 7*s.* 6*d.* net.

THERE is no end to the number of philosophical or quasi-philosophical puzzles with which the present-day physicist may divert himself; the marvel is that, in all the pother and hurly-burly of questioning of fundamentals, there remain a few calm souls content to weigh and to measure, unperturbed by the dust raised by iconoclasts who question the very possibility of exact measurements.

"The Itch of Disputation will prove the Scab of the Churches," said an apophthegmatical Provost of Eton more than three hundred years ago. The correctness of view of those who describe, in similar vigorous terms, the grammars of science which pour from our presses in ever-increasing numbers, may be questioned; always provided that we measure first, and theorise about it afterwards, there is much to be gained, and nothing to be lost, by hurling shards at dogmas which seemed, a generation ago, fixed and unassailable.

Moreover, the layman wants to know all about it; his papers proclaim that the universe is dissolving into radiation, that the author of the universe is a mathematician, that the principle of free-will has invaded physics, that there is not 'a particle of evidence in favour of determinism'; and we are told that things not observable are not real, and must be omitted from our theorisings—an assertion which, like many of these novel sayings, is not so new as it appears to be; the schoolman who told us *de non existentibus et non apparentibus eadens est ratio* had the root of the matter in him.

A certain amount of looseness of definition is apparent in some of the topics which are occupying the attention of theorists, and one suspects that no small number of the disputes that have arisen would prove to be verbal if the protagonists would only define carefully such terms as *indeterminism* and *free will*. Uneasiness in these matters of definition is to-day, curiously enough, more apparent in the biological than in the physical sciences, and it is interesting to note that, with a certain hesitation, the suggestion has been made that botanical science might possibly be the better for the loss of the *Reiss-begriff*. This is perhaps going too far, even though plant physiologists may, in the past, have attached queer connotations to

the notion; define your terms strictly and stick to the definitions, is a two-century old piece of advice, which represents the most profitable line of action.

Prof. Levy's contribution to the study of these problems merits careful attention. It is well fitted, in its clarity of style and in the elementary nature of its exposition, to the needs of the amateur in these matters. Mayhap he may be a trifle bewildered at first, for Prof. Levy's attitude is distinctly not that of the indeterminist school. Indeed, he roundly says that "the interpreters of the new knowledge and understanding, Sir James Jeans, Sir Arthur Eddington, Professor Millikan, General Smuts . . . have almost without exception approached their problems against a background of outworn Idealist Philosophy, none the less significant in its colouring because it has been unobtrusively though tacitly present. The pendulum has swung in the opposite direction. It is a reaction against the confident materialism of a past generation, as dogmatic and as uncritical as was its religious counterpart."

Which is very well; but we could wish that writers of all shades of opinion would furnish themselves with accurate critical and historical knowledge ere they attempt to see the present against the background of the past. What is this "confident materialism" against which an already "outworn Idealist Philosophy" has reacted? If the allusion is to the *Kraft-und-Stoff* movement of the mid-nineteenth century, it must be remembered that its vogue was short, and while sciolists might and did continue to rail against the 'dead mechanism' of the universe described by science, Buchner's book read oddly enough even to a young inquirer of the later eighteen-nineties. Mach and Pearson had already pointed the way to a saner synthesis which is certainly not outworn in the nineteen-thirties.

Scientific methodology—and with this attitude Prof. Levy is, we think, in agreement—is as deterministic, in the philosophic sense, as ever it was. Even the uncertainty principle is envisaged in terms of the mechanical pushes and pulls to which our macroscopic world has accustomed us, and the uncertainty is an uncertainty of the *where* and *when* rather than an uncertainty produced by a breakdown of the law of causality itself.

Such topics, and the deductions therefrom, are of great interest to the present-day world, and the author handles them in vigorous and stimulating fashion. His writing abounds in apt allusion and illustration, and the chapter on mathematics, which is written in an endeavour to show to those unfamiliar with the science "how mathematical methods are used as an instrument in scientific discovery", is an admirable piece of elementary exposition. His second chapter will be read with considerable interest. It passes the compass of any one man's mind to see as a whole the moving shadow-shapes that constitute his perceptual universe, and, in the nature of the case, whenever he studies a portion of that universe, he must make what the author terms an 'isolate' of it. Such a necessary isolation bears with it philosophical consequences which are discussed in some detail.

One or two minor omissions require notice; it is curious, in such a work, to find no detailed treatment of the terms 'cause' and 'causality'; Heisenberg's name is not indexed, and there is no reference to the uncertainty principle; Mach receives no mention, and Pearson is referred to twice, on topics quite incidental to the major issues.

There is no finality in these matters, and Prof. Levy has contributed but one more term to an unending series; his contribution is, however, both scholarly and important, and will compel the interest alike of the layman and the expert.

ALLAN FERGUSON.

Short Reviews

The Heart of England. By Edward Thomas. (Open-Air Library.) Pp. xvi + 228. (London and Toronto: J. M. Dent and Sons, Ltd., 1932.) 3*s*. 6*d*. net.

IT would be difficult to conceive of a more apt title to this collection of exquisite open-air essays than that chosen by the author, whose little volume is by its very simplicity and fragrance bound to appeal to many readers, especially of natural history, as being something that will live. The author must indeed have been inspired when he took up his pen to describe with such vivid directness his impressions of the country he loved so well. To use his own words: "You exult because you are alive and your spirit possesses this broad, domed earth."

The book is divided into five parts: "Leaving Town", "The Lowland", "The Upland", "The Mountains", and "The Sea". After reading such a volume as this it is with a feeling akin to consternation to realise that though the first publication was in 1906 it was not reprinted until 1932. English literature indeed lost one whom it could ill afford to spare when Edward Thomas was killed in Flanders during the War.

Air Ministry: Meteorological Office. British Rainfall, 1931: the Seventy-first Annual Volume of the British Rainfall Organization. Report on the Distribution of Rain in Space and Time over the British Isles during the Year 1931 as recorded by over 5,000 Observers in Great Britain and Ireland. (M.O. 345.) Issued by the Authority of the Meteorological Committee. Pp. xxi+306. (London: H.M. Stationery Office, 1932.) 15*s.* net.

FOR the British Isles as a whole the rainfall of 1931 was 109 per cent of the average, the year being the ninth in succession with a general fall in excess. Over the country as a whole the rainfall of 1931 was less than that of 1930 but greater than that of 1929. In spite of the wet summer some places in south-east England had less than the average annual fall, and so did the north-west of Scotland where summer was dry, but a wet area with more than 130 per cent embraced the north English Midlands.

As in 1930, and, indeed, every year, there were some notable downpours which, however, were unusually frequent. These included the severe thunderstorms of May 27 in south-west England and south Wales, the widespread intense rains of June 14, the day of the Birmingham tornado and of a destructive cloudburst near Bootle in Cumberland, the long succession of torrential rains in August amongst which was the thunderstorm that on August 8 deluged Boston in Lincolnshire with 6 in. of rain, the Whitby floods of September 4 which were comparable with those in the same district on July 20 in the previous year, and finally the heavy falls in the west of November 3 when 7 in. fell at Trecastle.

Special articles discuss long rainfall records and the effects of unsuitable sites for rain and evaporation gauges. L. C. W. B.

(1) *Post-Primary Science.* By W. F. F. Shearcroft. Book 2: Second Year's Course. Pp. 234. (London, Bombay and Sydney: George G. Harrap and Co., Ltd., 1931.) 2*s.* 6*d.*

(2) *Practical Science for Seniors.* By G. W. Manfield. Book 1. Pp. 96. 1*s.* 4*d.* Book 2. Pp. 128. 1*s.* 6*d.* Book 3. Pp. 160. 2*s.* (London: Macmillan and Co., Ltd., 1932.)

(1) This book is arranged in a somewhat unusual manner. It is divided into sections instead of the customary chapters, though more than one section is taken to deal with each branch of physics. Exercises alternate with the text in each section. They are printed in heavier type than the text, which is unfortunate as one is accustomed to associate heavy type with important information. The contents of the present volume include sections on gases, the atmosphere and atmospheric pressure, expansion of gases, liquids and solids, elementary mechanics, heat and elementary biology.

(2) These three booklets describe experiments in those branches of physics which have an important bearing on everyday life. Whenever possible, home-made apparatus of a simple nature is used. Instructions accompanied by clear illustrations make the assembly of the necessary apparatus an easy matter. Those pieces of apparatus which cannot conveniently be made at home are given with their approximate cost in a useful list at the beginning of each booklet. Short notes on the experiments are given at the end of each lesson. Book 1 contains experiments in elementary mechanics, on air, water and heat. Book 2 gives further experiments in mechanics and also experiments on air-pressure, water-pressure, light, magnetism and frictional electricity. Book 3 is devoted entirely to experiments in electricity. They are handy little books dealing with practical work only.

Winter Nights Entertainments: a Book of Pastimes for Everybody. By R. M. Abraham. Pp. ix + 186. (London: Constable and Co., Ltd., 1932.) 5*s.* net.

MR. R. M. ABRAHAM has brought together a very large number of examples, with illustrations, of card games and tricks, paper folding, coin and match tricks, string figures and tricks, knots and splices, games for the agile, toys, problems, etc., which will amuse those of all ages who like mental and digital dexterity to while away tedious hours of convalescence.

The making of string figures by primitive peoples is very widely spread and, as the author notes, it has engaged the attention of many field-workers. One would have thought that the author would have taken this opportunity to point out their real interest and to indicate where other examples may be found; instead of this he gives no references, though he has gleaned string figures mainly from Kathleen Haddon's (Mrs. Rishbeth) books. The process of making these has been modified in most cases, usually a new title has been substituted, and the localities have been omitted. For example: The tern is called the flying bird; the Apache door, the hurdle; the well, the fruit blossom; a temporary grass hut, is turned upside down to represent a parachute; the fly, crushing the cocoanut (*sic*)—a difficult feat!; the butterfly, the snail; the porker (described by Prof. Compton), the galloper (horse). Certainly the author has played tricks on the original discoverers of these string figures and on his unsuspecting readers. A. C. H.

Imperial College of Science and Technology: Huxley Memorial Lectures, 1925–1932. Pp. iii+12+30+38+27+16+21+28. (London: Macmillan and Co., Ltd., 1932.) 2*s.* 6*d.* net.

THE seven memorial lectures on different aspects of Huxley's life and work which are here collected give a very readable and impressive picture of the influence which T. H. Huxley still exerts in the field of science. It may be true that, as Aldous Huxley remarks in correcting G. K. Chesterton,

"Huxley *is* more of a literary than a scientific man", but while in one sense as a scientific man Huxley is now a mere historical figure, in another sense his influence as a man of science is still profoundly felt. The impetus he gave to scientific ways of thinking, not merely in some specialised field such as biology but also in the everyday affairs of life, has not yet died out. The battle he joined on the place of scientific method in education is still unfinished but his teachings and example are as inspiring as ever. The publication of these lectures in more permanent form should make known to a wider circle of scientific workers something of the sincerity and the humility which characterised Thomas Huxley, and should encourage them to take part in the yet unfinished warfare which he waged for scientific leadership and to emulate his own felicity of exposition of the aims and results of scientific studies. R.B.

Botany for Schools: a Textbook suitable for School Certificate and similar Examinations. By Dr. E. R. Spratt and A. V. Spratt. Pp. viii+363. (London: University Tutorial Press, Ltd., 1932.) 4*s*. 6*d*.

THE course of botany contained in these pages is claimed to cover completely the syllabus of the various School Certificate examinations. The authors also claim that the book is "suitable for the general reader who is interested in studying and experimenting with plants". Few textbooks are of interest or use to the 'general' reader; and this definitely is a textbook. A two years' botanical course is developed along orthodox lines. The photographs are good and are genuinely illustrative of certain botanical facts. The line diagrams, however, leave much to be desired, and in a number of cases they are misleading. The subject matter is presented in an appropriate form, but in places, especially the experimental physiology, it tends to be rather out of date.

As an examination textbook this work can be recommended, though it can scarcely be considered ideal or novel enough to be substituted for some of the better-known textbooks on the subject.

Bees, Wasps, Ants and Allied Insects of the British Isles. By Edward Step. (The Wayside and Woodland Series.) Pp. xxv + 238 + 111 plates. (London and New York: Frederick Warne and Co., Ltd., 1932.) 10*s*. 6*d*. net.

NO one who has read with interest the author's former well-known contributions to the "Wayside and Woodland" series could fail to welcome this, his last addition. The book is not claimed to be a rigid textbook on the Hymenoptera but sets out to give a general idea of these insects to field-naturalists. Therefore the treatment has necessitated the consideration of insects with no special regard to the natural sequence of groups, and only the more noticeable or important insects are fully described. A classified index of families and genera of the Hymenoptera is, however, appended. There are, also, a glossary of technical terms and a good general index. Step's books always have made good, interesting reading, but this, especially from the point of view of the profuse illustrations, can be looked upon as his *magnum opus*.

The Imperial Gazetteer of India. Vol. 26: *Atlas.* New (revised) edition. Published under the Authority of the Government of India. Pp. vii + 66 maps + 41. (Oxford: Clarendon Press; London: Oxford University Press, 1931.) 17*s*. 6*d*. net.

THE last edition of this atlas was published in 1909 and is now out of date in many respects. The present edition has two more plates than the old, the additions being an extra map of the distribution of crops, thus allowing twelve crops instead of eight to be shown, and one of Bihar and Orissa. Considerable changes have been made in the archæological sketch map, in the plate showing economic minerals and in the numerous town plans, and all the maps have been revised. In addition to the twenty-nine plates of general distributional maps, there are nineteen plates showing the whole of British India, the native States and Burma on a scale of 1 to 4,000,000. Afghanistan is shown on a small scale. There is a lengthy index.

How I was Born: the Plain Story of Birth and Sex. By Cyril Phillips Bryan. Pp. vii + 105. (London: John Bale, Sons and Danielsson, Ltd., 1932.) 5*s*. net.

IN this book, Mr. Bryan makes a sensible and interesting contribution to the literature of sex and its human significance. He gives a plain and straightforward statement which could be read with advantage by both adolescents and adults. There is nothing of a pornographic or even emotional character in the book, but much information which should afford wise guidance to healthy life and parentage. Among the many subjects clearly discussed are birth-control, sex determination, maternal impressions, inbreeding and heredity, hybrids and venereal disease. Many common fallacies are unveiled and curious cases described. In every respect the author has been successful in his endeavour to place before general readers the main facts relating to the whole range of sex.

Detachment of the Retina: a Contribution to the Study of its Causation and Treatment. By J. Ringland Anderson. Published for *The British Journal of Ophthalmology*. Pp. xiv + 207 + 7 plates. (Cambridge: At the University Press, 1931.) 20*s*. net.

IN his foreword, Sir John Parsons truly describes this monograph as being exhaustive and reliable and likely long to remain the chief source of information on detachment of the retina. Dr. Anderson gives a clear account, with full bibliographical references, of the present state of our knowledge of the causation and of the empirical mode of treatment which in certain cases affords some measure of success.

The Redwoods of California: The Past in the Present

By Prof. A. C. SEWARD, F.R.S.

THOUGH much has been written on the Big Trees of the Sierra Nevada and the Redwoods of the Californian Coast Range, the subject of these impressive examples of links with the past is by no means exhausted. It was my good fortune to wander in several Redwood groves in the spring of this year. Through the generosity of Dr. J. C. Merriam of the Carnegie Foundation and under

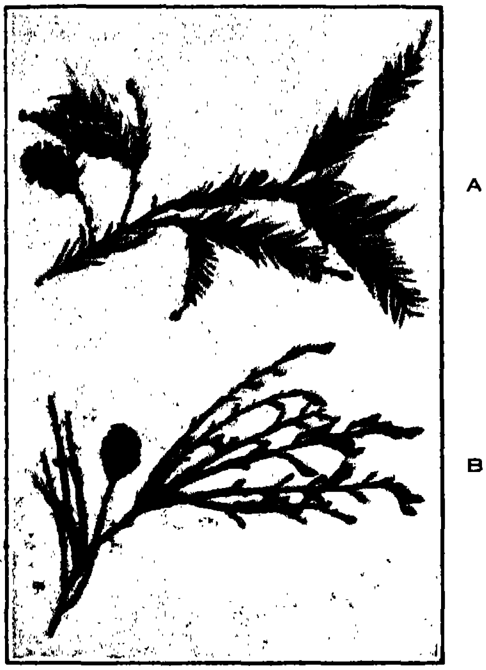

FIG. 1.—A, normal (two-ranked) foliage shoot; B, abnormal shoot of *Sequoia sempervirens* ($\frac{1}{2}$ natural size).

the expert guidance of Prof. Ralph W. Chaney of the University of California, Berkeley, visits were paid to the large groves north of San Francisco; and as guests of Prof. G. J. Peirce of Stanford University to the Big Basin south of San Francisco near the southern limit of the Redwood belt.

The two living species of *Sequoia* (Sequoyah, a Cherokee Indian who invented an alphabet), *Sequoia gigantea*, sometimes called *Wellingtonia*, the Big Tree, and *S. sempervirens*, the Redwood, are familiar as cultivated trees in British parks and gardens: it is the latter species with which this article deals. The Redwood was introduced into England soon after 1840 (the exact date is uncertain) and some specimens already exceed 100 ft. in height: this species is characterised by the red colour of the wood and soft, fibrous bark; foliage shoots with spirally disposed linear leaves, $\frac{1}{4}$–$1\frac{1}{4}$ in. in length, recalling those of the yew, which in the normal lateral branches are twisted by the torsion of the short stalks into two rows in one plane. On some leading branchlets and occasionally on abnormal lateral branches the leaves are shorter, more ovate and spiky and retain the spiral disposition. Though the normal two-ranked shoots are readily distinguished from those of *Sequoia gigantea*, abnormal branches bearing more tapered and scale-like leaves are very similar to the typical branches of the Big Trees. The ellipsoidal cones of *S. sempervirens* are surprisingly small, $\frac{3}{4}$–1 in. long and $\frac{1}{2}$ in. broad; they consist of 14–24 seed-bearing woody scales. The cones of *S. gigantea* are of the same form but rather larger. A typical foliage shoot and an abnormal shoot are shown in Fig. 1.

Extending more than half the length of the State of California lies a broad and relatively dry plain through which the Sacramento and San Joaquin Rivers flow respectively south and north into San

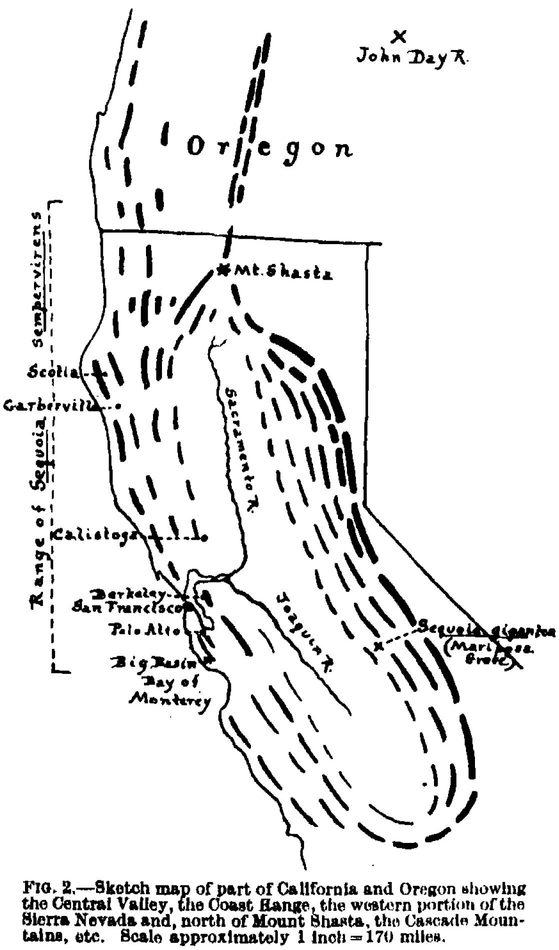

FIG. 2.—Sketch map of part of California and Oregon showing the Central Valley, the Coast Range, the western portion of the Sierra Nevada and, north of Mount Shasta, the Cascade Mountains, etc. Scale approximately 1 inch = 170 miles.

Francisco bay. The Sierra Nevada, including the highest mountains in the United States, form the eastern boundary, and the lower parallel ridges of the Coast Range lie between the western edge of the central valley and the Pacific Ocean. *Sequoia gigantea* is confined to a few localities on the Sierra Nevada, the most famous of which is the Mariposa Grove (Fig. 2): *S. sempervirens*, which has 'a

stronger hold upon existence', occupies a much larger territory to the west of the valley, from Monterey County in the south to a few miles north of the California-Oregon boundary, a distance of about 450 miles and with an average breadth of twenty miles. The Redwoods range from sea-level to an altitude of 3000 ft. Their distribution is not continuous. In some places the Redwoods form pure stands; there are forests in which the Douglas fir and other conifers are common associates; and areas in which the Redwood is absent either through human agency or from natural causes. A solitary giant by the side of the railway near Stanford University and the small town of Palo Alto (so named from the tree) is a conspicuous landmark.

A good road, the Redwood Highway, runs through the forests north of San Francisco and traverses a succession of groves which have been gradually acquired by the State, substantially aided by the Save-the-Redwoods League. Up to March of this year, nearly 30,000 acres of forest had been saved from destruction.

The climate of the Redwood belt varies within comparatively narrow limits; the temperature rarely falls below 15° F. and though it is said to rise to 100° F. or rather more, the average is 50°–60° F. From May to October is a dry season; actual precipitation as rain is confined to the wet season, November–April. The annual rainfall is usually between 20 in. and 60 in., though in places it occasionally reaches 100 in. During the dry months the forests bordering the coast receive an abundant supply of water from the dense clouds of fog which roll eastwards over the coast range hills. It is the summer fog—'the wet-winged angel of the rain'—which provides the humid atmosphere essential to the Redwoods.

Though surpassed by the Big Trees in girth, the Redwoods reach a greater height. One sees conflicting statements on the rival claims of the Redwoods and the Australian gum trees (*Eucalyptus*) to be described as the tallest in the world: the late Mr. J. H. Maiden of Sydney believed the Redwoods to be taller than the gum trees; some American botanists say that the Australian trees are the taller. But whether or not the Redwoods have longer stems, they are more majestic and make a stronger appeal to the imagination. It may be that in the future the alien eucalypts, which already play a conspicuous part in the Californian landscape, may exceed in height the native conifer. The highway on the north side of San Francisco bay passes through typical Californian scenery for several miles; low hills with smoothed rounded contours studded with clumps of live oak (*Quercus agrifolia*); on the lower ground sheets of the native blue and white lupin (*Lupinus bicolor*) and scattered patches of the glorious California poppy. Redwoods were first seen from the highway about thirty miles south of the small town of Garberville, with its typical 'main street', 230 miles north of Berkeley. Farther north we drove through miles of reserved forest areas, grove after grove of Redwoods with Douglas firs as their most striking companions. Between Garberville and Scotia, Redwoods are crowded on the hill slopes and along the deep valleys, where a fringe of alders, willows, and other trees forms the lowest zone of vegetation. Looking down from the steep hill-sides to the river-bed one sees weather-beaten and bleached stems and branches piled by the river in flood against obstructing rocks or stranded on banks of gravel, samples of contemporary vegetation on their way to entombment in river-borne sediment. Towering above the general level of the forest on the high rocky ridges, spires of *Sequoia* and *Pseudotsuga* (Douglas fir) were silhouetted against the blue sky; the more drooping branches of the Redwood forming a contrast to the straighter arms of the fir.

FIG 3.—A Redwood forest: the large tree is 54 ft. in circumference, 6 ft. from the ground. (Photograph by Dr. A. A. Cannon)

The black oak (*Quercus Kelloggii*), the tan oak (*Lithocarpus densiflora*), the Californian lilac (*Umbellularia californica*), the Madrõno (*Arbutus Menziesii*), representing in the new world the strawberry tree of the Killarney Lakes and the Mediterranean flora, easily recognised by the red polished bark, the mountain dogwood (*Cornus Nuttallii*), maples and many other trees are some of the commonest neighbours of the Redwoods. A pink oxalis (*Oxalis oregona*), *Trillium*, the poison oak (*Rhus diversiloba*), irises, the red columbine (*Aquilegia truncata*), sword ferns (*Polystichum munitum*), the lady fern, and the far-flung bracken are a few of the abundant plants on the forest floor.

It is difficult to realise the height of the taller Redwoods in forests where there are few or no standards of comparison. Some of the giants, if

transplanted to the Close at Salisbury, would reach to within a few feet of the top of the famous spire. There are few trees equal to the Redwoods in resistance to fungus diseases, insect pests and forest fires: the thick fibrous bark and the wood, which in healthy trees lacks resin-ducts, are almost indestructible. The ordinary method of reproduction is vegetative, not from seed: the trees have remarkable capacity for regeneration by suckers from the roots. One often sees a ring of tall trees with a huge broken or charred stump in the centre of the circle: the moribund parent had developed a group of suckers which in course of time gained independence. A prone stem draped with nests of sword fern and many flowering plants may form a plinth bearing slender

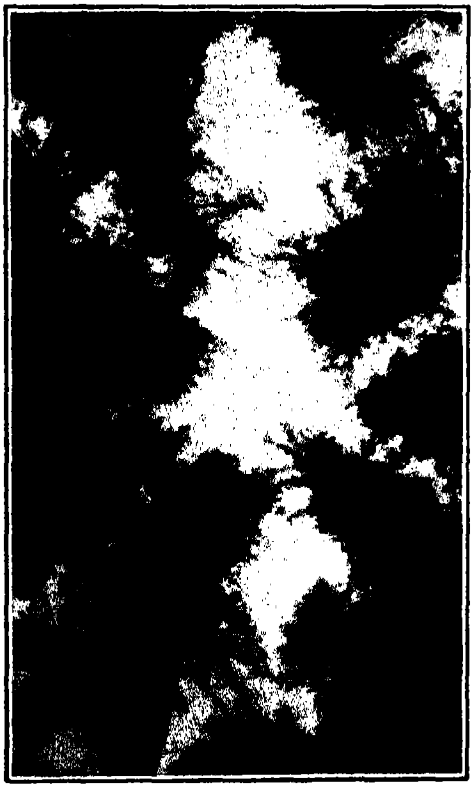

FIG. 4.—The canopy in a Redwood forest showing the sky pattern. (Photograph by Dr. A. A. Cannon.)

columns of young Redwoods. In the Big Basin, one specimen known as the Chimney Tree is a hollow trunk 100 ft. high, in which several people can stand and look upwards to the sky through the open end: the wood has been almost completely destroyed by fire; the shell still bears many vigorous branches.

On many of the trees are large and small burls, rounded excrescences like great warts, which are sold as souvenirs; when sawn off and placed with the flat surface in a saucer of water and wet moss, the dormant buds grow into an encircling wreath of two-ranked foliage-shoots.

It was not until we came to Scotia that the preserved areas were seriously interrupted by hill-sides bare of all but charred stems and comparatively young trees which had grown from the roots of felled parents: the older trees were being sawn in the mills of a lumber company into huge planks.

The Redwoods appeal to us by their superbly fashioned columns, impressive examples of perfect architectural construction, bearing tapering cones of massed branches (Fig. 3); tree separated from tree in the distant canopy by small fringed spaces open to the light of the sun and to the sea fogs from the west (Fig. 4)*. They make an appeal as living things—some of them have been growing where they stand for twenty to thirty centuries—linking the present with a prehistoric past: groups of trees already centuries old surrounding ancestral relics bear witness to the continuity of the race through ages still more remote. At Calistoga, seventy miles north of San Francisco, one sees striking examples of petrified Redwoods, more than 100 ft. in length and 8 ft. in diameter, in beds derived from some Pliocene volcano, and with the stems have been found cones and foliage indistinguishable from those of the living species. It is easy to visualise a continuous series of generations linking the present with the latter part of the Tertiary period. In places where a Redwood climate prevailed, there is no reason to assume any substantial change in the forest flora of western America through the many thousand years of this small fraction of geological history. Nor, as we shall see, is there any evidence of essential difference between the Redwoods and their forest associates and the trees and shrubs which lived in California and Oregon in the middle of the Tertiary period, say fifty million years ago.

From an intensive study of some of the older Tertiary floras in Oregon, Prof. Chaney has shown that the striking contrasts revealed by a comparison of the Oligocene and recent floras of Britain are not found in western America. The Oligocene and Miocene plants described by Prof. Chaney were collected from localities in the John Day basin a little to the east of the centre of Oregon (see Fig. 2). Two of the floras—the Bridge Creek flora of Oligocene age and the Miocene Mascall flora—suffice to illustrate the appropriateness of the application to the Redwood flora of the phrase, 'the past in the present'. These floras have much in common but the elements of the Mascall flora indicate less humid conditions and greater exposure to light. More than 20,000 specimens from the Bridge Creek beds were examined and tabulated; and for comparison 8000 specimens of leaves, twigs and other scraps gathered from contemporary stream deposits in a canyon in one of the preserved areas (Muir Woods), where sediment is being deposited at bends of the river. In the Bridge Creek flora there are four dominant species, *Sequoia Langsdorfii*, *Alnus carpinoides*, *Quercus consimilis*, *Umbellularia* sp., which make up 86·44 per cent of the whole: in the recent stream

* I am indebted to Dr. A. A. Cannon of Stanford University for the photographs reproduced as Figs. 3 and 4.

deposits the corresponding species, *Sequoia sempervirens*, *Alnus rubra*, *Quercus densiflora*, *Umbellularia californica* constitute 85·44 per cent of the total number of species.

It is customary to speak of the Tertiary *Sequoia* with two-ranked leaves as *S. Langsdorfii*; but it may well be specifically inseparable from the existing Redwood. The plants of the Mascall flora are preserved in diatomaceous shale above the Bridge Creek beds and separated from them by sheets of lava. Several trees, such as species of *Quercus*, *Sequoia Langsdorfii*, *Umbellularia*, *Salix*, *Acer*, *Cornus*, *Rhus*, *Cerocarpus*, and many others have representatives in the Redwood forests, while there are several other plants which have their modern counterparts in eastern America and elsewhere. The resemblance of the Bridge Creek flora to that of the present Coast Range forests is much closer: among conifers *Pinus*, *Tsuga*, *Sequoia* and *Torreya* are common to both; among flowering plants *Myrica*, *Corylus*, *Alnus*, *Quercus*, *Berberis*, *Umbellularia*, *Fraxinus*, *Acer*, *Rhamnus*, *Cornus* and many others, all linking the Oligocene and recent floras by closely related species.

In the course of the gradual desiccation, since the Oligocene age, of the northern part of the Great Basin—the region through which flows the John Day River—most of the characteristic Redwood associates have disappeared from Oregon, though they have survived in the more humid belt on the western seaboard. The Bridge Creek flora, which is one of many examined by Prof. Chaney and his co-workers, is an example of an association still found in the Redwood belt; and in essentials it agrees with Tertiary floras recorded from Switzerland, Greenland, Spitsbergen, Siberia and Manchuria. We know that *Sequoia* flourished in Mid-Tertiary England, in the arctic regions as far north as Ellesmere Land, over a large area in Europe and the Far East, and in many parts of the New World. Why is the genus now confined to a narrow strip of California? No satisfying answer has been given: Prof. Chaney believes, and he is probably right, that "emergence and the consequent withdrawal of epicontinental seas have played an important part in the restriction of the Redwood forests".*

It is impossible in a single article to do more than direct attention to the nature of the work now being done on the reconstruction of some of the Tertiary floras of the New World and their comparison with floras of the present day. From Alaska through British Columbia, Washington and the States farther south are scattered vast stores of plants waiting to be collected and described; there are also large collections in Canadian museums. This field of work is exceptionally rich in promise: it is certain that by adopting the methods so successfully and convincingly employed by Prof. Chaney, who studies the extinct side by side with the recent floras and follows the latter beyond the southern boundary of the United States into Central and South America, it would be possible to follow the development and vicissitudes of the plant-world over nearly the whole length of western North America. Abundant material is available; the workers are lamentably few.

* For fuller information on the Bridge Creek, Mascall and other Tertiary floras and their relation to the modern Redwood Forest, see R. W. Chaney's papers in Publication No. 349 of the Carnegie Institution, Washington, 1925. Also a paper in Publication No. 346, 1927.

Relations between Pure and Applied Science*

By Sir JAMES BAILLIE, O.B.E.,
Vice-Chancellor of the University of Leeds

THERE is still a certain amount of misunderstanding of what applied science means, especially on the part of those who draw a hard and fast line between pure and applied science, or of those who tend to regard applied science as of subordinate scientific interest and importance. There are some who treat applied science with a certain disparagement as being an attempt to adapt science to commercial purposes, a means of increasing wealth rather than of increasing knowledge. This attitude of mind is not perhaps so widespread as it used to be, but it still exists in Great Britain. Institutions such as the younger universities, which from the first seriously took up investigations which fall within the scope of applied science, have on that account been held to have derogated from the traditional conception of universities. Certainly up to recent years in Great Britain, no such problems were considered to deserve the attention of the academic mind. It was in fact for long held to be a recommendation and a merit that universities only taught and investigated subjects which could be studied in order to acquire knowledge for its own sake, and were useless otherwise except as promoting mental discipline.

It is instructive to observe that this narrow and indefensible outlook on knowledge is changing, and that the older universities are now taking a prominent and leading part in the advancement of applied science. We have only to recall in this connexion the important investigations carried on in both the older universities in the department of agriculture, and the work done in Cambridge to solve the difficult practical problems of cold storage. The institution, a few years ago, of the Department of Scientific and Industrial Research with its corollary, the setting up of the industrial research associations, is rapidly modifying and

* From a paper entitled "Applied Science in Yorkshire" read before Section L (Educational Science) of the British Association at York on Sept. 5. In addition to the extracts here printed, dealing with the relationships between pure and applied science, the paper outlined the development of technical instruction of all types in Yorkshire, and the work of the three industrial research associations which have their headquarters in the county, as well as that of special departments instituted in the Universities of Leeds and Sheffield to promote particular industries.

will in time completely transform the former attitude of the public and academic mind to applied science. When the history of universities in Britain comes to be written, it will be found that not the least of the contributions made by the younger universities to the development of academic life is that they led the way in recognising the scientific value and interest of applied science.

Applied science is neither more nor less than an investigation in the laboratory of the processes which are involved in the adaptation of Nature to the service of society in one form or another—a purpose which is surely eminently important and desirable. Some of these processes have been carried on empirically and with relative success for generations, to the great advantage of mankind. A large amount of experience has been accumulated and handed on by tradition, custom and instruction; but such experience has not been critically examined in the light of and by means of scientific method and resources. So far as rules have been arrived at in this way, the experience acquired rests on what we may call rule of thumb. The purpose of applied science is to substitute the rule of scientific law for the rule of thumb.

In other cases the laboratory examination of Nature's processes and material may lead and has led to the discovery of ways and means of adapting Nature to man's service in directions which have not been thought of in the past. In these cases the knowledge of the laws discovered by science precedes the adaptation of Nature's resources to man's use. New industries and manufactures may arise as the result of the antecedent work of the scientific investigator. Even here it must not be assumed that the application of science ceases to be science when the science is applied. The application consists in carrying out in detail the general laws discovered by science; and this in principle is in no way different from the process of verification by practical test which is an essential characteristic of scientific method. In other words, the application of science is a process of science as much as the discovery of the laws which are applied for man's service. Whether, therefore, the process of using Nature for man's ends precedes investigation by the scientist, or scientific investigation precedes and gives rise to the application of Nature to man's ends, is merely a matter of history and does not affect the meaning of applied science.

Applied science is thus quite distinct from the industrial and commercial development of the results of scientific investigation. This development depends on other considerations;—whether the capital is available to commercialise the results, whether anyone has the imagination and resourcefulness to produce an article which will appeal to the public, or whether the adaptation of the results for the use of man is economically profitable at a given time. Faraday's discovery of magnetic induction was of immense potential service to man, but it required time and genius of another order than his to foresee the ways and means to make it available for man's convenience.

Applied science does not differ from pure science by presenting a less difficult problem or by being less scientific than pure science. The sole differentia is that in the former case the results can promote man's desire to bend Nature to the service of the social life of man, while in the latter there is no such reference, at least directly or in the mind of the investigator while carrying on his investigation. The one aims at the active control of Nature, the other at the reflective comprehension of Nature. Both are essential to the fulfilment of man's life, and equally important ways of manifesting the supremacy of mind over Nature on which civilisation rests. Neither is subordinate to the other; and, as experience shows, they reciprocally assist one another, just as any science may produce results of value to another science. Sometimes we find that discoveries in pure science lead to new developments in applied science; sometimes achievements in applied science give suggestions for further investigations in pure science. Indeed there is no pure science, however apparently remote from social welfare, which may not in the long run promote the aim of applied science.

Apart from the fact that it is important to make clear the significance of applied science, the foregoing statement has a direct bearing on the subject with which the paper deals. For the development of applied science in Yorkshire has been governed by the recognition that effective control over Nature's processes, whether carried on in established industries or not, can only be secured by scientific investigation in the strictest sense. In the universities of Yorkshire in particular, applied science and pure science departments have been established from the first alongside one another. This has not been a mere accident, but a settled policy which, for the reasons given, must be considered to be as sound in principle as it has been fruitful in its results, both to the students of science and to those engaged in scientific investigation. The same policy has been adopted in the case of the higher technical colleges in Yorkshire, for example, those of Bradford and Huddersfield, where good work has been done not only on behalf of applied science but also in pure science.

No doubt in the early stages of the history of applied science in Yorkshire primary importance was attached to the practical usefulness of science for technical processes rather than to pure science. The practical mind of Yorkshire was inclined in the first instance to appreciate science for its value in furthering an intelligent interest in the productive industries of the area. This was but natural and not unreasonable; and since those concerned for the promotion of industrial welfare by means of science were, in general, not themselves trained in science, but had heard of or foreseen its value, it was perhaps inevitable that

the conception of applied science was understood in a comparatively narrow sense, as investigation and instruction in the craft side of industry and in the scientific subjects which seemed relevant thereto. The craft side is certainly an essential aspect of applied science, and must always be so if science is to be applied at all. It was only later and rather slowly that it was realised that this aspect merely sets the problem of applied science and that the understanding of the craft does not provide a solution of the questions which industrial processes raise. Still, even this humble beginning gave the start to what has provided a vast scientific undertaking.

The establishment of the Universities of Leeds and Sheffield, which represents the culminating point in the institutional development of applied science in Yorkshire, created new standards and a new outlook in the conception of applied science and its value for industry. Hitherto, applied science in the widest sense had been restricted to the communication of information on and the study of the technique of industrial processes carried on in the area, with some instruction of a rather elementary kind in certain of the pure sciences. The aim was to train or provide craftsmen with an intelligent appreciation of the rules and operations of their respective crafts, so that there might be in industry more competent and efficient workmen. With the advent of the universities and the spirit of detached scientific inquiry which inspires university work, applied science was able to become the critic and investigator of traditional industrial processes and methods, and to place the resources of a wider scientific outlook and knowledge at the service of craftsmanship. This raised instruction in applied science to a higher intellectual level. It could not be merely the communication of traditional knowledge acquired by experience in industry; its aim was not simply to confirm but to transform existing practice in industry by training whole-time students in scientific principles and by promoting scientific investigation of industrial processes. This could not but be to the ultimate advantage of industry though the effects might not be seen for some time and the results might be slow in appearing.

The prosecution of applied science at this higher level had a further important consequence; it suggested and indeed created a graded system of technical training and education with craft instruction in its various forms at one end of the scale and specialised scientific investigation into industrial processes at the other. The first could be appropriately taken over by the technical colleges, the second by the universities. There is at points a certain overlap, perhaps inevitable, between the work of the technical colleges and the universities. But the main distinction is clear between the purpose of the two types of institutions occupied with applied science. The primary business of the technical college is to provide craft teaching at a lower or a higher level, with higher scientific instruction and research occupying relatively a second place in the work of the college; the main purpose of the university is to provide higher teaching in science and to carry on scientific investigations in applied science, with technical instruction occupying relatively a secondary place in its work.

Obituary

SIR BERNARD MALLET, K.C.B.

SIR BERNARD MALLET, whose death on October 28, at seventy-three years of age, we regret to record, was the son of Sir Louis Mallet, a distinguished civil servant. He first entered the Foreign Office, from which he was transferred to the Treasury. He became a commissioner of Inland Revenue in 1897 and Registrar General in 1909, from which post he retired in 1920. His chief assistant for many years was Dr. Stevenson, who did such admirable statistical work in connexion with *inter alia* the differential birth rate, labour which never received adequate reward from the Government in spite of the loyal advocacy of his chief. Sir Bernard was president of the Royal Statistical Society in 1916–18, where, as everywhere, his personal influence was most valuable. He was for long an official of the Political Economy Club, and at its dinners must have met every living economist of note. He wrote several books, including a continuing series on the British budgets.

During the last years of his life, eugenics and the cognate subject of population occupied much of Sir Bernard's time. As to the latter, he was president of the World Population Conference held at Geneva in 1927, as a result of which was inaugurated the International Union for the Scientific Investigation of Population Problems, a now flourishing organisation in which he has continued to play an active part. He was a member of the International Federation of Eugenic Organisations, and attended meetings at Paris, Munich and in Dorsetshire. This last was somewhat of a novelty, the head-quarters being at the house of his cousin, Capt. Pitt-Rivers. A paper by him was read at the International Congress at New York this year.

Sir Bernard joined the Council of the Eugenics Society in 1918 and became its president in 1928. About that time the Society received a large bequest from an Australian pastoralist, the exaggerated hopes thus aroused in truth causing no small trouble. The Society prospered greatly under his guidance, the progress made in regard to sterilisation being especially noticeable, whilst several new schemes were set on foot, of which the most noteworthy was the attempt to give practical definition and expression to the concept of negative eugenics both in the sphere of hereditary

diseases and in that of the so-called 'Social Problem Group'.

That characteristic of Sir Bernard Mallet which will have stamped itself most strongly on the minds of all his friends is the charm of his personality. He was a gentleman in the very highest sense of the word. He was always courteous and most helpful to his colleagues. Eugenics as an applied science demands not only theoretical knowledge but also the power to judge between conflicting human motives, needs and prejudices, with the result that the task of its leaders is at times one of extreme difficulty. The Eugenics Society was fortunate in securing the services of a president with such varied experiences, all of which helped him to fill with success the place which he only consented to occupy out of a sense of duty.

PROF. K. K. GEDROIZ

SOIL investigators all over the world will learn with deep regret of the death on October 5 of Prof. K. K. Gedroiz of the Dokuchaiev Soil Institute, Leningrad, and until lately president of the International Society of Soil Science. He was born in 1872 in Bessarabia, was educated in Kief and graduated in 1897 as a forest engineer at the School of Forestry in Leningrad. He then became assistant to Kossovitch at the Agro-chemical Laboratory of the Ministry of Agriculture. In 1915 he was appointed editor of the Russian *Journal of Experimental Agriculture*, and in 1919 was made professor of soils at the School of Forestry: later on, in 1922, he became lecturer in agricultural chemistry at Nossov, and after Glinka's death in 1928 he was elected a member of the Russian Academy of Science and director of the Dokuchaiev Soil Institute, where he was specially concerned with the laboratory investigations of the soil and also with the soils of the podsol zone.

Prof. Gedroiz for many years carried out important investigations on the process of absorption by soil, attributing it, as van Bemmelen had previously done, to complex reactive substances produced by weathering. Both in their composition and their interaction with dissolved salts these substances were generally so similar in type that he felt justified in speaking of a reactive 'soil complex' modelled on the same lines as a salt, in which the cations could be replaced by other bases or by hydrogen. In the 'complex' of a normal fertile soil the predominant cation is calcium; in other soils it might be sodium, magnesium or hydrogen. In developing these ideas he was able to give a rational explanation of many of the phenomena associated with acid and alkaline soils, and to clear up many obscurities in what had previously been a very difficult subject.

Prof. Gedroiz's work was long unknown to British and American investigators owing to its publication in Russian. A summary issued in an abstract journal attracted the attention of one or two United States soil workers and they arranged for a translation of all of his papers into English. The volume was widely circulated among other soil investigators and at once ensured the recognition of the high merits of his work.

Gedroiz did much to make Russian soil science famous throughout the civilised world. His investigations into the soil complex and the phenomena of absorption fell easily into line with the studies on soil formation and classification initiated by Dokuchaiev and continued by a group of brilliant successors, Glinka, Neustruev and other workers still surviving: it gave a new and permanent direction to soil science. Gedroiz was of a modest and retiring disposition, rarely appearing at scientific gatherings: many soil investigators who visited Russia in 1930 were disappointed that they were unable to meet him and pay their respects to him. His work had sterling qualities which will ensure its place among the classics of modern science. E. J. RUSSELL.

DR. WILLIAM GARNETT

THE death of Dr. William Garnett on November 1, at the ripe age of eighty-one years, will cause a feeling of the very deepest regret to those of his contemporaries and coadjutors who knew and appreciated the man and his genius.

Dr. Garnett was born at Portsea on December 30, 1850, and was the son of William Garnett of that town. He received his early education at the City of London School, and continued it at the Royal School of Mines, having taken the first place among the Whitworth scholars in 1869. He afterwards proceeded to St. John's College, Cambridge, of which he was later elected a fellow, having been bracketed fifth wrangler in 1873. He was the first demonstrator of physics in the Cavendish Laboratory under James Clerk Maxwell, whose biographer he became.

Fortunately for the cause of technical education, Dr. Garnett left Cambridge and associated himself with the developments of education which were then taking place. He was exceptionally well qualified to take up the position of a leader in the movement which was then developing throughout the length and breadth of the country for the advancement of what was termed 'technical education'. He held the position of professor of mathematics, physics and mechanics at University College, Nottingham, and later became principal and professor of mathematics in the Durham College of Science, Newcastle-upon-Tyne. Here he did splendid work. Realising that it was most important to associate the educational authorities with the development of technical education, he to some extent laid on one side his teaching duties at Newcastle-upon-Tyne with the view of obtaining an association between his college and the education authorities. He likewise found time during this period to write on behalf of technical education in the *Technical World* and other journals.

It was only natural, therefore, that Dr. Garnett

should be appointed secretary and educational adviser to the London County Council Technical Education Board in 1893. In this position, he probably achieved his most important work. He was largely responsible for the development of the London polytechnics and worked in harmony with both the City Parochial Charity Trustees and the great City companies. When the old Technical Education Committee was superseded by the London County Council Education Committee, Dr. Garnett was appointed educational adviser, and although this position relieved him of the responsibility of much educational routine, he exercised a great influence.

Dr. Garnett had a personality which was felt by all who were brought in contact with him. In his presence, none could fail to realise that they were dealing with a man of force of character, ideals and originality. He had, moreover, the power of inspiring devotion in those with whom he was associated. J. L. S. H.

WE regret to announce the following deaths:

Prof. U. S. Grant, professor and head of the Department of Geology and Geography at Northwestern University, Evanston, Illinois, who has done much work in economic and petrographic geology, on September 21, aged sixty-five years.

Prof. A. B. Hill, emeritus professor of hygiene and public health at the University of Birmingham, president of the Society of Medical Officers of Health in 1911–12 and of the Association of County Medical Officers in 1917–1924, a leading authority on national public health, on November 5, aged seventy-eight years.

News and Views

Royal Society Medallists

HIS MAJESTY THE KING has approved of the following awards this year by the President and Council of the Royal Society in respect of the two Royal Medals: A Royal Medal to Prof. R. Robinson, for his distinguished work in organic chemistry; A Royal Medal to Prof. E. Mellanby, for his distinguished work on dietary factors, especially in connexion with rickets. The following awards of medals have also been made by the President and Council: Copley Medal to Dr. G. E. Hale for his distinguished work on the magnetic field of the sun; Rumford Medal to Prof. F. Haber for his distinguished work in the application of thermodynamics to chemical reactions; Davy Medal to Prof. R. Willstätter for his distinguished researches in organic chemistry; Darwin Medal to Dr. C. E. Correns for his distinguished researches in genetics; Buchanan Medal to Prof. T. Madsen for his distinguished theoretical and practical work on immunity, especially in relation to diphtheria antitoxin; Hughes Medal to Dr. J. Chadwick for his distinguished researches on radioactivity.

Barnaba Oriani, 1752–1832

THE centenary falls on November 12 of the death of the eminent Italian astronomer, Barnaba Oriani, who for many years was director of the Milan Observatory, and to whom Piazzi communicated his discovery of the minor planet Ceres. Piazzi first observed the planet on January 1, 1801, and a few weeks later he wrote to Oriani and Bode, the former of whom calculated its orbit. Oriani was born near Milan on July 17, 1752, and was educated by the Barnabites. He was made a priest at the age of twenty-three years and almost immediately entered the Observatory, which had not long since been founded at the College of Brera, Milan. He soon attained a recognised place among Italian astronomers and was among the first to publish tables of the planet Uranus, discovered by Herschel. In 1786 he was sent to London to obtain instruments from Ramsden. At this time he became acquainted with Herschel, with whom he afterwards corresponded. With his colleagues, Francesco Reggio (1743–1804) and Angelo Cesaris (1750–1832), he carried out geodetical operations in northern Italy. He published various works on the motion of the planets. Although, during the greater part of Oriani's life, Milan formed a part of the Austrian dominions, it was seized by the French in 1796, and in 1802, the year in which Oriani was made director of the Observatory, it became the capital of the Cisalpine republic, with Napoleon as first president. On this occasion, it is said, that on Oriani's refusing to take the oath swearing hatred against monarchy, the wording of the oath was accordingly altered for him. Oriani's successors at Milan have included Carlini, Schiaparelli and Celoria.

Atomic Projectiles

ATOMIC projectiles and their applications formed the subject of the nineteenth Thomas Hawksley lecture delivered by Lord Rutherford on November 4 before the Institution of Mechanical Engineers. At present the maximum velocity that can be communicated to matter in bulk is not more than two miles a second. This is of the same order of magnitude as the average speed of the molecules of gases under ordinary conditions. But if we turn to individual charged atoms, methods have been developed which enable us to produce atomic projectiles moving with enormous speed. When the velocity becomes comparable with that of light, we have to take into account the change of mass of the particle with speed. As the velocity is generally produced by the acceleration of the particle in an electric field, it is convenient to speak of a thousand-volt particle, meaning thereby that the particle has the speed and energy equal to that gained in passing freely between two points differing in potential by a thousand volts. In the experiments of Cockcroft and Walton in the Cavendish Laboratory, Cambridge, a steady difference of potential up to 600,000 volts can be

maintained in the accelerating tube, thus producing a stream of swift protons corresponding to a current of 20 micro-amperes. By the multiple acceleration of charged atoms, Lawrence and Livingston in California have been able to obtain a stream of protons of energy so high as 1,200,000 volts by the use of a voltage so low as 4,000 volts.

Effects of Atomic Bombardment

IN the second part of his address, Lord Rutherford described the applications of atomic projectiles. After considering the way in which swift α-particles from radioactive substances have been used for throwing light on the dimensions of the atomic nucleus, he gave an interesting account of experiments on the transmutation of matter. This has been effected by the bombardment of matter by swift atomic projectiles of different kinds. In 1919, Rutherford was able to demonstrate the disintegration of the nitrogen nucleus as a result of a close collision with an α-particle in which a swift proton was expelled. The discovery of the 'neutron' followed upon experiments by Bothe, who observed a very penetrating type of radiation when beryllium was bombarded by α-particles. Chadwick carried out further experiments by counting methods, and concluded that the radiation consists of a flight of material particles which are supposed to be close combinations of a proton and an electron. Within the last year, Cockcroft and Walton have obtained definite evidence that certain atoms can be transformed by a stream of fast protons produced artificially in a discharge tube. This new method of attack, so successfully begun, is certain to give us much new information on the structure of nuclei and the problem of the transmutation of the elements.

Egypt and the Nile

THE presidential address delivered by Sir Murdoch Macdonald to the Institution of Civil Engineers at the first meeting of the session on November 1 was almost entirely devoted to a consideration of the engineering development of Egypt and the Sudan, with which his life work has been closely associated, and, in particular, to the measures taken to bring into cultivation vast areas of waste land which have lain unproductive for centuries. Of the 360,000 square miles over which the King of Egypt rules, 95 per cent is desert. The combined area of the two cultivated districts of Lower and Upper Egypt is only about 12,000 square miles, one tenth of the area of Great Britain and Ireland; and the narrow strip of cultivated land, running for some 550 miles on each side of the Nile from Cairo to Assuan, has an average width of not more than 6 miles. Referring to the geological history of the country, Sir Murdoch said that, on the supposition that the Delta of the Nile lay in an ancient bay of the Mediterranean now filled with silt, the original mouth of the river was at Cairo. The depth of silt and sand in that locality indicates that the river once ran at a much lower level than it does now. From records of water levels on the Roda gauge, near Cairo, extending over many hundred years, it has been deduced that the bed of the river and the general level of the cultivable land must have been raised at the rate of 1 mm. a year and the process has been going on probably for 20,000 years.

Irrigation Schemes in Egypt and the Sudan

AFTER alluding to ancient indigenous methods of providing water for crops, Sir Murdoch Macdonald proceeded to discuss the modern system of perennial irrigation (under which provision has also to be made for drainage) adopted in consequence of the introduction of cotton cultivation by the Khedive, Mohammed Ali. The first work of construction in that connexion was the Delta Barrage, completed in 1861, but, owing to defects in the foundations, not brought into effective use until the British occupation, when the works were strengthened. The succeeding structures of the same type at Assuan, Asyut, Esna and Nag Hammadi were historically noticed, and then reference was made to various schemes put forward from time to time for impounding the water of the Blue Nile and the White Nile above Khartoum. Figures were quoted to show the benefit to Egypt of the Assuan Dam. The 1,000 million cubic metres of water originally impounded would be increased by the re-heightening to at least 4,800 million cubic metres and the normal summer supply would be increased by about 66 per cent. The contemplated Gebel Aulia reservoir would contain about 3,000 million cubic metres and would possibly be able to pass 2,500 million into the river. A Lake Albert Dam, only 8 metres in height, would impound about 40,000 million cubic metres, but would require to be coupled with works which would conserve the waters as they passed down the river and prevent their being wasted as at present in the Sudd region. Sir Murdoch touched upon the schemes put forward for preventing the immense loss of water due to evaporation from the marsh formed by the main stream between the Sobat and Bahr-el-Ghazal. The whole territory including the marsh region has an area of about 90,000 square miles and might become a wonderful timber growing country. Summing up the position between Egypt and the Anglo-Egyptian Sudan, he said that the large volumes of water passing in flood, of which Egypt can only use a small part, would make it possible for the Sudan to divert a great quantity without detriment to her neighbour. All the conceivable diminution by future reservoirs would not be sufficient to reduce the flood volume below the known requirements of Egypt for the fertilisation of its flood crops.

Telephony and Telegraphy in Great Britain

SIR THOMAS PURVES, engineer to the Post Office, contributes to the British Industries Number forming a supplement to the *Times* of November 1 an interesting article on the industries connected with telegraphy and telephony. In the earlier days of telegraphy, Great Britain was pre-eminent in the manufacture of high quality Morse and Wheatstone automatic apparatus. The very fact of the excellence

of this equipment somewhat delayed the adoption of type-printing telegraphs in Great Britain, but the whole supplies of the telegraph system are now being manufactured at home. It is hoped that the establishment of the teleprinter exchange service which is being introduced by the Post Office as an adjunct to the public telephone switching system will produce a further extensive demand for these ingenious machines. Before the year 1912, when the telephone service of Great Britain was transferred to the Post Office, a large portion of the equipment was purchased from abroad. Now the proportion of foreign material purchased by the Post Office is less than one per cent of the whole. A great impetus was given to the mass production of apparatus on precision principles in 1922 by the general adoption of standardised types of automatic exchanges. This policy encouraged other nations to follow suit and export markets to several countries were opened up for automatic telephone equipment manufactured in Great Britain. The circuits and mechanisms developed for automatic exchanges opened up independent fields of application in other directions, such as the supervisory control of electrical power plant, centralised railway control and the electrical equipment of the totalisators now operating on racecourses. Telephone manufacturers were quick to take advantage of these applications.

Telephone Development

THE economic blizzard from which the world is now suffering has affected the rate of telephone development in Great Britain to a smaller extent than in any other of the principal nations. Sir Thomas Purves states that the net increase per annum in Great Britain in recent years has been about 125,000 stations. In the last complete year (1931–32) it fell to 84,000. Nevertheless, it is the largest increase recorded in any country of the world for the same period. For the whole of Europe, outside of Great Britain, the net increase was less than 200,000. In some countries the number of cessations of service exceeds the number of new subscribers and a net loss is registered. In North America, for example, the net loss is about 550,000 stations. For the current year, it is probable that there will be a net increase in Great Britain of about 80,000 and that many of the countries of Europe will show actual losses. In America there will be a large loss. If a revival of trade occurs, the telephone development of Great Britain will go forward by leaps and bounds. In the matter of underground, telegraph and telephone cables, Great Britain has been from the first a pioneer. For building open telegraph and telephone lines it is still necessary to depend on Norway and Sweden for slow-grown raw timber. English and Scottish mountain pine and Canadian and Australian timber have proved disappointing. The use of poles of metal and concrete has been investigated on numerous occasions, but so far the cost of these alternatives has proved prohibitive. The timber used for general construction purposes is obtained entirely from home and Empire sources. The whole of the extensive radio plant and apparatus for long-distance communication used by the Post Office is of British manufacture.

Recent Developments in the Utilisation of Electricity

IN his inaugural address as chairman of the North-Western Centre of the Institution of Electrical Engineers, Mr. G. F. Sills discussed a very large number of recent developments in the utilisation of electricity. One of the most important and most promising of electric devices is the mercury arc rectifier. When supplied with direct current, it can be made to generate alternating current voltage at any frequency. It can also supply direct current when supplied with alternating current. It provides a link between a.c. and d.c. systems which works either way. Batteries can thus be used as a reserve on a.c. systems. One of the most important applications is to feed single-phase railways from a three-phase system at a different frequency. The standardisation of systems of supply for electric railways is thus not likely to lead to much trouble, as by the aid of the rectifier any kind of electric supply can be converted into any other. By its use it will soon be possible to transmit power by high-voltage direct current and this will lead to considerable economies in transmission. Obstruction lights are now being placed on power lines for marking obstacles along airways. They generally consist of neon tubes operated either at high or low voltages. They are used also to indicate high buildings and wireless masts. The light gives a large splash of red colour and is easily distinguished from other lights near the ground. Another interesting application is the reading of consumers' electric meters by means of telephone lines, the connexion being made through the power company's connexion with the telephone exchange. A device for indicating the presence of a dangerous amount of coal gas is also described. It works automatically, closing an alarm circuit, and it can be made to switch on an electric fan to clear the dangerous area.

Manufacture of Lenses

THE presidential address of Mr. W. Taylor to the Institution of Mechanical Engineers on October 28 was mainly devoted to the application of mechanical engineering to the production of lenses, particularly photographic lenses, which to-day are made by the tens of thousands. One of the characters of mechanical engineering, he said, is the extraordinary accuracy regularly attained in its best products. One thousandth of an inch is approximately the limit of accuracy which can be attained in the ordinary machining of metal with cutting tools, one ten thousandth the order of accuracy by grinding and lapping; but in making the best photographic lenses and other optical instruments of precision, the accuracy of the surfaces of the elements, such as lenses, prisms and mirrors, must be from one hundred thousandth to a few millionths of an inch, and this accuracy is attained in everyday working, not only by skilled artist craftsmen, but also by less skilled

persons doing repetition work by the aid of special appliances, the products of mechanical engineering. In the course of his address, Mr. Taylor referred at length to the functions and designing of lenses, the properties and the production of optical glass and the various workshop processes by which lenses are cut, ground, polished and tested. It was in connexion with work on photographic lenses that the need was felt for screw-threads much more accurate in form, more free from pitch and periodic error, and this in turn led to improved technique of screw-thread measurement, gauging and generation.

Andrew Laing Memorial Lecture

THE winter session of the North-East Coast Institution of Engineers and Shipbuilders was opened on October 21 by the delivery at Newcastle-upon-Tyne of the presidential address by Mr. R. J. Walker, who since 1899 has been associated with the Parsons Steam Turbine Co., Ltd., of which after the death of Sir Charles Parsons he became chairman and managing director. At the following meeting of the Institution, held on October 28, Engr. Vice-Admiral Sir R. W. Skelton, the Engineer-in-Chief of the Fleet, delivered the first Andrew Laing lecture. Laing, who was born in Edinburgh on January 31, 1856, and died in Newcastle on January 24, 1931, from 1877 until 1896 was connected with the Fairfield Shipbuilding and Engineering Co., Govan, and from 1896 until the time of his death was managing director of the Wallsend Slipway and Engineering Co. His life's work was mainly connected with the design and construction of the machinery of Atlantic liners, his most famous ship being the *Mauretania*, built in 1907, which for twenty-three years held the 'blue ribbon' of the Atlantic. The construction of this vessel and her ill-fated sister ship the *Lusitania* was due to circumstances somewhat akin to those existing to-day, when the fastest vessels in the mercantile marine are not registered as British vessels. The initial step was the formation of an Admiralty committee in 1902 which was directed to inquire into the principles on which subsidies were being given and to consider how and at what cost vessels could be secured which should combine great speed with a large radius of action. The outcome was an agreement between the Government and the Cunard Co. whereby the Government agreed to advance a sum of money at 2¾ per cent interest for the construction of two ships and to increase the annual subsidy. The bold step of adopting steam turbines for the vessels was due to the report of a technical committee on which Laing served.

Memorial to Sir Gregory Foster, Bt.

A FUND has been raised for the establishment of a memorial to the late Sir Gregory Foster, at College Hall, London, a hall of residence for women students in the University with which he was connected for more than thirty years, during twenty-one of which he was chairman of the Council. The memorial has taken the form of the provision of teak doors throughout the public rooms of the new building for the Hall recently erected in Malet Street and to be opened by H.M. the Queen on November 10. A memorial tablet designed by Mr. Brook Kitchin has also been placed in the entrance hall and bears a record of the services rendered by Sir Gregory Foster. A portrait painted by Mrs. Macleod has now been finished and has been hung in the council room of the Hall. It represents the sitter not as his friends knew him in the last years of his life, but as he will be remembered by those who knew him in the fullness of his strength and vigour, thus providing an interesting comparison with the portrait recently painted by Sir William Orpen which hangs in University College. The memorial tablet was unveiled on November 4 by Sir Alexander Gibb, who succeeded Sir Gregory Foster as chairman of the Council of College Hall. About a hundred or so of those who had subscribed to the memorial fund were present, and for the greater number of these the occasion presented the first opportunity of seeing the new building, which in itself is the greatest and most lasting memorial to Sir Gregory Foster's work in providing increased residential accommodation for the students of the University of London.

Huxley Memorial Medal and Lecture

THE presentation of the Huxley Memorial Medal of the Royal Anthropological Institute for 1932 to Prof. C. G. Seligman will take place on November 29, when Prof. Seligman is to deliver the Huxley Memorial Lecture at 8.30 P.M. Prof. Seligman is already a medallist of the Royal Anthropological Institute, having been awarded the Rivers Memorial Medal for 1926 in recognition of his work in the field in New Guinea, among the Veddas of Ceylon and in the Sudan. Prof. Seligman gained his first experience of field work as a member of the Cambridge University Expedition to the Torres Straits in 1898 under Dr. A. C. Haddon. He visited New Guinea again as joint leader of the Cooke-Daniels Ethnographical Expedition in 1904, publishing his results in "The Melanesians of British New Guinea" (1910). His studies of the Veddas in 1907, in which he was assisted by Mrs. Seligman, were published as "The Veddas" in 1911, while the results of his investigations among the Sudanese tribes on several occasions, on which he has again been accompanied and assisted by Mrs. Seligman, are announced for publication at an early date. The study in the University of London of the customs and races of man has made substantial advances during Prof. Seligman's occupation of the chair of ethnology at the London School of Economics, especially in the promotion and organisation of training for colonial officials.

Scientific Expedition to Tibet

IN February 1933 Capt. F. Kingdon-Ward is setting out to explore what is perhaps the least-known part of Tibet—the arc of mountainous country which lies between the bend of the Tsangpo-Brahmaputra and the bend of the Salween. The route to be followed is: the Assam valley, Sadiyà, Lohit valley, Rimà, up the Rong Thod Chu, over the Ata Gang Pass (16,000 ft.)

to Shurdin Gornpa, in lat. 29° 30′ N., long. 97° 0′ E., where a base camp will be established at 13,600 ft. altitude. From here the collecting work will be done. This is the cross-roads of Asia, the meeting place of four floral regions, the Central Asian, Sino-Himalayan, Indo-Malayan, and Eastern Asiatic; and it harbours the richest alpine flora in the world. The flora of this area should in fact throw light on both the earlier east and west distribution of plants across south-eastern Asia, and on the later north and south distribution, down the Malay Peninsula, brought about during the last glacial epoch. The predominance of the former is difficult to account for if we assume the Himalayan uplift to stop short at the Tsangpo bend, or to curve southwards at this point. On the other hand, if the Himalayan axis is prolonged eastwards, the Salween River must cut across it in a very deep gorge, and should moreover cross at a point of maximum elevation, precisely as the Indus and Tsangpo do. These are matters for investigation. Thus both botanical and geographical work will be done. These are closely related, and each illuminates the other. The botanical collecting will be done on behalf of the Department of Botany of the British Museum.

Weather Information to Aviators in India

THE India Meteorological Department has set out a complete account of the arrangements in force for the supply of reports on existing weather and of anticipated weather to aviators flying over any part of an immense area which includes not only India but also the Persian Gulf coast east of Bushire, Baluchistan and Burma (India Meteorological Department. Meteorological Organisation in India for the Supply of Weather Information to Aviators. Pp. iii+27. (Calcutta: Government of India Central Publication Branch, 1932.) 12 annas; 1*s*. 3*d*.) There are five main forecasting centres, at Karachi, Calcutta, Poona, Peshawar and Quetta. The first three centres are organised with a view of issuing reports and forecasts to civil aviators, and the last two deal mainly with the requirements of the R.A.F. The local centres also number five, namely Rangoon, Akyab, Dum Dum, Allahabad and Jodhpur. There would normally be available at such local centres information about the force and direction of the wind up to a height of 10,000 feet. There is another type of distributing centre—the pilot balloon station—of which there is a relatively large number. These are aerodromes or landing grounds with observers who make soundings of the upper atmosphere with pilot balloons, and are able to supply the information about upper winds so obtained to aviators on request, and presumably are also largely responsible for supplying such local information on this subject as is required at the more important centres. The information given in this pamphlet appears to include everything that can possibly be required by aviators, including the times of issue of the regular broadcasts, all necessary codes, and the wave-lengths, together with detailed instructions as to the procedure for obtaining special reports while in flight.

Galvanometer Mirrors for Sound Recording

IN the variable width method of recording sound on film, a galvanometer is used in which a loop of metal ribbon, 0·005 in. broad and 0·0005 in. thick, is placed between the poles of a permanent magnet, a small mirror being cemented across the two arms of the loop. When speech currents from the microphone and amplifiers pass along the ribbon, the mirror vibrates and causes the reflected beam of light to traverse a narrow slit at right angles to the direction of motion of the film, and thus trace a graph of the sound waves. Since the upper limit of reproduction from the ordinary talking film projection apparatus is about 6000 cycles per second, the natural frequency of oscillation of the galvanometer must be at least as great as this. The inertia of its moving parts must, therefore, be low. The mirror must be as light and small as possible. It should also be accurately surfaced and silvered in order to ensure uniform reflection. The production of such mirrors is an interesting piece of optical work involving manipulative processes on a different scale from that employed for the usual products of the manufacturing optician. Mirrors made by Messrs. Taylor, Taylor and Hobson, Ltd., Stoughton Street Works, Leicester, specially suitable for these galvanometers, are rectangular in shape and measure 0·032 in. by 0·018 in. by 0·004 in. The glass from which they are made is first cut to the correct size and then optically worked on both sides. The back surface is silvered by cathode sputtering and is protected by a suitable varnish. The finished mirror weighs 0·0001 gm.

Memorial to Laplace

L'Astronomie for September contains a panegyric on Laplace, delivered by Dr. E. Esclangon, director of the Paris Observatory, on the occasion of the unveiling of a statue of the famous astronomer at Beaumont-en-Auge on July 3. Dr. Esclangon observes that Laplace is justly called the French Newton; while basing his work on Newton's law of universal gravitation, he carried the results of this law very much further than any of his predecessors. Special mention is made of his detection of the cause of the lunar acceleration arising from the diminution of the eccentricity of the earth's orbit. He also made useful researches on the theory of the tides; and his famous nebular hypothesis, though no longer held in its original form, at least as regards the solar system, was a valuable contribution to cosmogony, and formed the starting-point of many other theories.

Reversion in a Hybrid Macaw

WHAT appears like a very striking case of reversion in a species-hybrid is related, in the *Avicultural Magazine* for September, p. 220, by A. Anderson, who describes a hybrid macaw bird in New Zealand this year between a male of the red-and-yellow and a female of the blue-and-yellow species. As one parent is red and the other yellow below, it is not surprising that the hybrid young bird shows both

these colours on the under-surface; what is strange is that the back is bluish-green, for the male is red here and the female blue, so that the green tint must be due to a return to a coloration ancestral in macaws, most of which are as a matter of fact green, though the more sensationally coloured species are those familiar in captivity. The case is similar to the appearance of a rufous-coloured and more ordinary bird resembling Hume's pheasant when the copper-red, white-pied Elliot's pheasant has been crossed with the Mikado pheasant, which is mostly black, and to the production of sheldrakes showing much smoky-grey pencilling similar to that on the Australasian farms when the rufous South African grey-headed sheldrake was crossed with the mainly-white European species, in both cases a more primitive and plain coloration appearing.

Announcements

THE following awards have been made by the Royal Aeronautical Society: Taylor Gold Medal to Dr. G. V. Lachmann for his paper entitled "Control Beyond the Stall", and the Busk Memorial Prize to H. Constant for his paper entitled "Aircraft Vibration".

THE following appointments have recently been made by the Secretary of State for the Colonies in the Colonial Forestry Services: Mr. D. Kinloch, to be assistant conservator of forests, Gold Coast; Mr. P. C. Randell, to be assistant conservator of forests, Nigeria.

THE following is a list of those recommended by the President and Council for election to the Council of the Royal Society at the anniversary meeting on November 30:—*President:* Sir Frederick Hopkins; *Treasurer:* Sir Henry Lyons; *Secretaries:* Sir Henry Dale and Sir Frank Smith; *Foreign Secretary:* Lord Rayleigh. *Other Members of Council:* Dr. J. A. Arkwright, Prof. W. L. Bragg, Prof. C. H. Desch, Dr. G. M. B. Dobson, Mr. A. C. G. Egerton, Dr. J. Gray, Prof. A. V. Hill, Prof. A. Hutchinson, Prof. J. E. Littlewood, Prof. E. Mellanby, Prof. R. Robinson, Dr. N. V. Sidgwick, Prof. A. G. Tansley, Prof. D'Arcy W. Thompson, Dr. W. Trotter, Mr. G. Udny Yule.

THE fourth of the series of exhibitions: "Photography in the Service of Mankind", at the house of the Royal Photographic Society, 35 Russell Square, London, W.C.1, will be devoted to kinematography. The exhibition will be opened on November 14 and will remain open until December 10. Much of the space available will be occupied by apparatus illustrating the historical development of kinematography and the various outstanding achievements on the mechanical side of the science. In addition to the exhibition proper, however, a series of eleven meetings has been arranged. These will illustrate, through the medium of films, the immense variety of ways in which kinematography touches modern life: salesmanship, medicine, natural history, general scientific research and education are among the subjects to be illustrated.

THE British Social Hygiene Council has arranged a national conference on "The Place of Biology in Education" to be held at the British Medical Association House, Tavistock Square, London, W.C.1, on November 30 and December 1 and 3, under the presidency of the Right Hon. Viscount Chelmsford. During the first morning session, besides the inaugural addresses of the president and patrons, the national and imperial need for a biological outlook will be considered. In the afternoon and on December 3, the promotion of the teaching of biology by local authorities and biology in training colleges, central, senior and elementary schools and in public, secondary and preparatory schools will be discussed. On December 1, a joint session will be held with the Central Association for Mental Welfare to discuss the problem of the social control of the feeble-minded child leaving the ordinary elementary school.

A CATALOGUE of an unusual sort of collection has been issued by Messrs. Dulau and Company, Ltd., 32 Old Bond Street, W.1. It contains lists of old prints in colour and line chosen chiefly for their decorative charm, and includes many items of interest to naturalists and others. Many are plates from standard works by such as Buffon, Levaillant, Pennant, Gould, at prices varying from 1*s.* to 30*s.*; hand-tinted sporting prints published between 1805 and 1807, at 35*s.* each; Loggan's copper-plate views of Oxford (1675) at 5*s.*–20*s.*; old maps, old coloured lithographs of the mansions of England by Joseph Nash (1869), portraits by Bartolozzi (1793–99), and sundry other prints making an interesting series of 353 items.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A junior assistant in the Museum and Art Gallery of the County Borough of Reading—The Curator (Nov. 12). A second engineering assistant in the Waterworks Department of the County Borough of Brighton—The Waterworks Engineer, 12, Bond Street, Brighton (Nov. 16). Examiners in practical mathematics, practical drawing and science of the preparatory senior technical course of the Union of Lancashire and Cheshire Institutes—The Secretary, 33, Blackfriars Street, Manchester (Nov. 21). A full-time assistant for electrical engineering courses at the Crewe Technical College—The Director of Education, Dept. 'C', County Education Offices, City Road, Chester (Nov. 23). Five assistant engineers in the Post Office Engineering Department—The Secretary, Civil Service Commission, Burlington Gardens, London, W.1 (Nov. 24). An assistant lecturer in physics at King's College (University of London)—The Secretary, King's College, Strand, W.C.2 (Nov. 28). An instructor in manual work and engineering at the King's School, Pontefract—The Headmaster. Grocers' Company research scholars in sanitary science—The Clerk, Grocers' Company, Grocers' Hall, London, E.C.2. A lecturer in elementary electrical engineering at the Borough Polytechnic, London, S.E.1—The Principal.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Down Pelage in the Ovidæ

THE woolly covering of the adult sheep, the fleece, is often considered to differentiate the Ovidæ from other mammals, and not less distinctive is the coat of the lamb. In most breeds of sheep the lamb is closely covered with a birth coat of small spiral tufts of fibres (Fig. 1). The tufts vary in size, the number and closeness of the spiral turns and their distance apart, all of which are characters having a bearing upon the fleece grown later. In addition, long hairy fibres protrude beyond the level of the tufts and, where plentiful, partly obscure or even replace them, as over the face, the under surface and down the legs. With the later growth of the fleece the spiral tufts are carried upwards, for the most part preserving their form and distinctness (Fig. 1), maybe until the first shearing at about fifteen months. In some cases, however, small successive fragments break away at the tip, particularly in the merino, where the identity of the tuft is lost within three or four months. The coarse hairy fibres are shed within the first months of the lamb's existence, and are generally replaced by fibres of a different type.

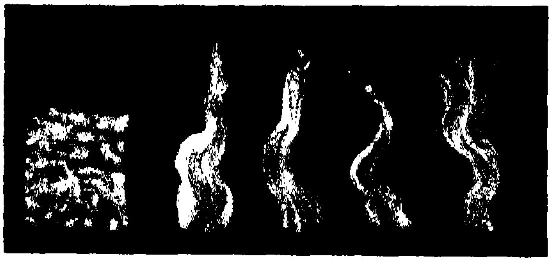

FIG. 1. Portion of skin of new-born Welsh Mountain lamb showing spiral tufts; also two-month staples of South Devon lamb with spiral tufts at apex, right staple opened out to show prototrichs.

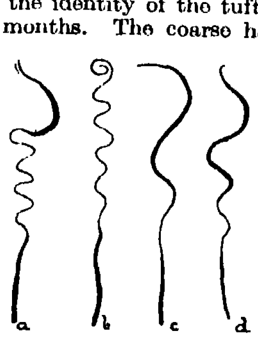

FIG. 2. Diagram of various forms of prototrichs continued into the thicker definitive fibre.

Attention has recently been directed to the constituent fibres of the spiral tufts, as possible guides to the later wool production. Different forms occur, some of which are shown diagrammatically in Fig. 2. Fig. 2*a* represents the most characteristic form. The fibre is at first sickle-shaped and thickens below the tapering tip, being medullated for a short distance. It then becomes very fine and curly before passing into the definitive fibre, which is usually thicker. The curls follow very closely the spiral turns of the tuft, as if moulded thereby. Fig. 2*b* shows another frequent form where the sickle thickening is wanting, and the whole fibre is fine and curly to the tip. All intermediate stages between the well-defined medullated sickle tip and the curly tip can readily be found, even in the same tuft, and the one can only be regarded as an attenuation of the other. The aggregate of sickle tips gives a stiff, beak-like apex to the tuft while the other has only a flat ending.

Among the coarse fibres of the belly and legs the tufts are more or less wanting and the sickle often assumes a whip-lash effect (Fig. 2*c*). Again, the thick medullated part of the sickle may, as it were, encroach to a greater or less distance on the fine part below (Fig. 2*d*) and even for the whole distance, appearing of the same thickness as the definitive fibre itself. Fibres of this character are to be found on the legs where the wool is largely replaced by coarse kemp fibres, and all transitional stages from true sickle fibres to kempy fibres are met with. Beneath the characteristic forms above described very fine short woolly fibres everywhere occur. The sickle tip of the fibres is doubtless to be associated with the fact that the new fibre does not at first emerge in a straight line with the follicle, but passes horizontally for some distance along the epidermis in the canal produced in connexion with the sebaceous gland. In general, the medullated sickle tips are followed by kemp fibres while the curly tips are continued as heterotypes and wool.

Sickle tipped medullated fibres from the birth coat of the merino were first described by me[1] and have since been found in the primitive coat of the Blackhead Persian and elsewhere,[2] while Dry has recently described both sickle tipped and curly tipped fibres from the Romney Marsh.[3] In the course of the present study they have been found on the birth coat of practically all the British breeds. Manifestly, in their different expressions, they are a truly distinctive feature of the birth coat, to be considered apart from the definitive fibres into which they are continued. It is submitted that they are best regarded as down fibres or prototrichs, comparable in many respects with the down which occurs at the apex of the definitive feathers in birds. The entire covering on the lamb at birth, the spiral tufts as well as the hairy fibres (halo fibres), would then be regarded as a down coat composed of prototrichs or down fibres, persisting for a time at the tip of the staples of the later woolly coat.

The constancy with which the medullated sickle tipped prototrich occurs suggests a phylogenetic significance. It is a fibre essentially coarse above and fine below and, having been produced *in utero*, the difference can scarcely be interpreted as a response to conditions other than those genetic in their nature. Fibres of the same differential character, which I have elsewhere termed heterotypes,[1] prevail among mammals generally. Thus mature fibres of the various mountain and long-woolled breeds among sheep show a greater or less indication of coarseness above and fineness below, to repeat itself year by year. Similar differences are found among most other domestic animals, dog, cat, horse, cattle and camel, and in the yak, jackal, seal, hare,

deer and bison. The coat tends to be coarse on the outside and fine below, but for the most part the change is effected in the individual fibre. It is manifest that heterotypism is to be regarded as the primary condition of the hair fibres in most mammals, carrying with it a physiological significance, and it is repeated in a simplified form in the down fibres or prototrichs of the Ovidæ. The curly tipped prototrichs are merely those which have lost their medullated thickening, and all stages are forthcoming from one extreme to the other, just as we have all stages towards complete medullation of the sickle fibre.

We thus arrive at the conception that the birth coat in the Ovidæ is a true down coat, a separate pelage of spiral tufts. The constituent fibres are distinct from the later definitive fibres, and are to be contrasted as prototrichs or down fibres. The stages shown by the prototrichs towards fine woolliness on one hand and coarse kempiness on the other establish the close relationship of the many different types of fibres met with in the Ovidæ (wool, heterotypes, garo, kemp) with those in other mammals where the pelage comprises gradations of only one type of fibre. The distinctive coat of the Ovidæ is brought into direct relationship with that of mammals generally; the component fibres of the two are but differentiations of a single type, even though for classificatory needs they may be grouped separately.

Weather Maps of the World

IN connexion with the special investigations arranged for the polar year, it is proposed to collect observations from sea and land in order to obtain effective charts for the whole of the northern hemisphere and perhaps, in time, of the southern hemisphere too.

The invitation to contribute observations is accompanied by an excellent outline chart of the northern hemisphere with contours of the land surface for 500, 1000 and 2000 metres.

The charts carry also, as specimens, meteorological information for the first week of March 1931, which includes isobaric lines over the sea, continued over the land as *sea-level* isobars. The practice of drawing isobars which, over the land, are merely hypothetical, has been customary in meteorological work now for some seventy years. Perhaps it began with north-western Europe where sea level is at least a near neighbour; but it has developed until, in the proposed charts, sea-level isobars are shown over the contours of the Rocky Mountains, the Alps, the Himalaya and Greenland, although sea level has a very restricted meaning for those countries and the change in the distribution of the meteorological elements with height is a primary meteorological problem.

The enterprise is a repetition, on a more advanced scale, of one which was undertaken by the Meteorological Council in connexion with the original polar year, 1882–3. All the available information for the Atlantic and adjacent continents was collected and plotted on well-known charts, published by the Council.

Incidentally, that enterprise led to a mistrust of the closed isobars round cyclonic and anticyclonic centres as the controlling powers in weather; a mistrust which in Great Britain we have never been able to shake off. It will be interesting to learn whether the jubilee of the polar year will reconstitute them or discredit them further.

A real question about weather charts for the world turns, however, upon sea-level isobars carried over the land irrespective of its elevation above sea level. It is undeniable that, by that practice, pressure is separated from its associates temperature, humidity and wind, and the student of weather is left more or less 'in the air' while space on the map is occupied by lines without any definite meaning.

The contours on the outline charts suggest that the enterprise offers a golden opportunity for a definite step in weather study.

The contour line of 500 metres rails off the enclosures in the northern hemisphere within which sea-level isobars are ineffective. Would it not be possible to prepare the maps in the usual way for the region outside those enclosures and invite the denizens of the several regions inside: France, Austria, Switzerland, Italy and the Balkans for one, India, Persia, Russia and China for another, the United States, Canada and Mexico for a third, each to contribute a map for their enclosure that they would think most appropriate for a region above 1 km. level?

Such an opportunity may never recur; and what would be a rather questionable enterprise for an individual member of the international partnership would be real generosity on the part of each group, contributing to the advancement of knowledge for the benefit of the whole.

It might even result in changing the choice of level for charts over the sea itself, and choosing 106 metres, where the normal pressure is 1000 millibars, as suggested years ago by Köppen, for we all know that the surface is apt to mar the effective features of the atmospheric circulation.

Heat Distribution in a Uniform Bar

THE theory of the potential distribution in a long cable when the head end is insulated after being maintained for some time at a steady potential has been given recently.[1] It was pointed out that the reasoning would apply equally well to the case of a long uniform bar which is allowed to cool after one end has been heated. The experimental confirmation of the theory is not easy in the electrical case owing to the fact that it is not possible to tap a long laid cable at intervals for the observation of the potential, and artificial lines are not available with the leakance sufficiently uniformly distributed. Moreover, the changes are very rapid, and in the practical example which was worked out in the above-mentioned paper, all transients had practically died away after the expiry of two seconds. In the heat analogue, on the other hand, the changes are very much slower and

the necessary apparatus (an ordinary 'Forbes bar') available in almost any laboratory.

In this case the expression for the temperature at any point distant x along the bar at time t after removing the source of heat is :

$$T_{x,t} = 2\,T_0\,l\sqrt{(RG)}\tanh l\sqrt{(RG)} \sum_{m=0,1,2\ldots} \frac{\cos\{(1-x/l)\,m\pi\}.\exp\left(-\dfrac{m^2\pi^2+GRl^2}{CRl^2}.t\right)}{(m^2\pi^2+GRl^2)\,(\cos m\pi+\sin m\pi/m\pi)}$$

where T_0 is the initial steady temperature at the end of the bar, R the heat resistance per unit length of bar, C the heat capacity per unit length of bar, G the rate of heat loss from surface per degree per unit length of bar, l the length of bar, and m is zero or any integer.

The bar used was of brass, and was furnished with eight holes, distant apart 10·15 cm. between centres. At one end there was a right-angled elbow joint, so

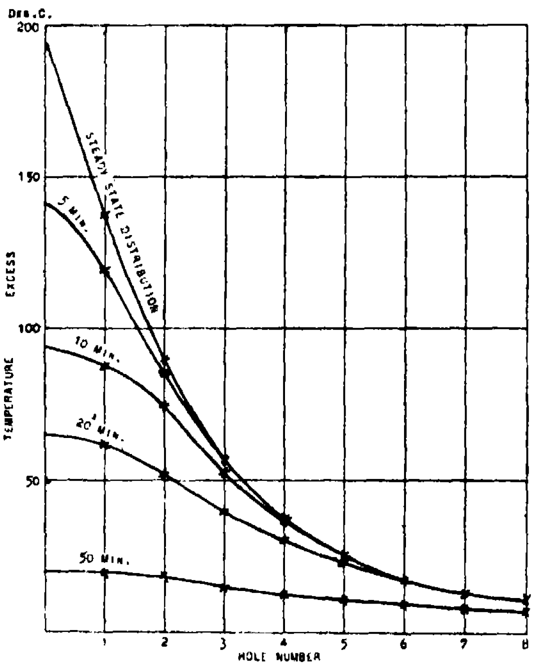

FIG. 1

that this end could be dipped vertically into a bath of molten solder while the main part of the bar was horizontal. The temperature observations were made on ordinary thermometers dipping into mercury contained in the holes along the bar. The mean distance from the centre of the first hole to the solder level was 9·4 cm. and the length of bar immersed 9·5 cm. The section of the bar was a square of 2·50 cm. side.

After keeping the end immersed for three hours in the solder bath, a uniform heat distribution was obtained and the heat source was withdrawn. The temperature at the various points along the bar was observed at regular intervals, giving the results shown in Fig. 1. This family of curves is of the same form as that obtained from theoretical considerations and shown in Fig. 1 of the paper referred to above.

Radiations from Radium D and E

DURING the past eighteen months, experiments have been carried out by Mr. W. J. Henderson and myself, so designed as to give us certain information about the radiations emitted by radium (D + E).

The first experiment, the initial results of which were reported at the 1931 meeting of the Royal Society of Canada, has shown that there is no evidence, in the case of radium E, for what have been called β-rays of high energy. We have used a suitable mixture of cardboard and lead, of total mass/cm.^{2} somewhat greater than the range, in order to reduce the ionisation in a cardboard-lined electroscope to one ninety-thousandth of its initial value. It is not a difficult matter to show that less than one per cent of this ionisation can be due to primary β-rays and hence that not one β-ray in 1,500,000 can belong to the group, with values of HR between 7000 and 10,000 reported by Curie and D'Espine.[1] This result gives a strong indication that β-rays of high energy are not emitted by any substance.

Henderson has examined the ranges of the β-rays of radium E in various substances and has found much larger values than previous observers. In cardboard the range is 0·52gm./cm.^{2} and in aluminium, tin and lead somewhat greater than 0·60gm./cm.^{2}. Among other things, these results indicate that if β-ray ranges are to be used to determine the end points of β-ray spectra, some convention must be adopted. One that might be useful would be to use aluminium as absorbing material and take the range as that mass/cm.^{2} which reduced the ionisation due to β-rays to one fifty-thousandth of its initial value and then calculate the end point from the data of Varder[2] on homogeneous rays. Applying this to radium E, the end point comes out at about HR = 5500. Further work is being done on this problem.

We have measured the absorption of the γ-rays in lead and have obtained estimates of the relative numbers of atoms emitting the different types of radiations, using the method of Gray and O'Leary[3]. A very soft type of γ-ray, presumably the M rays characteristic of atomic number 83, has been detected. L rays are emitted by about thirty per cent of radium D atoms and primary rays by somewhat less than four per cent, a value in fair agreement with those obtained by Bramson and Stahel and Sizoo[4]. The primary rays consist apparently of a band extending from $\lambda < 0{\cdot}28$A. to $\lambda > 0{\cdot}30$A., the average mass absorption coefficient in lead being 12. An initial attempt to detect this band by crystal reflection was unsuccessful. The bearing of our results on problems connected with the emission of β-rays from radium D will be discussed elsewhere.

The properties of the hard γ-rays of radium E are so similar to those of the X- or secondary γ-rays produced in other elements by the β-rays of radium E that I am of the opinion that they are entirely secondary in character, that is, that they are excited by some of the β-rays after their escape from the nucleus. They are emitted by about one per cent of the disintegrating atoms.

Mercury Traps

THE interesting investigations of Messrs. Hughes and Poindexter[1] showed that a trap lined with alkali metal is as satisfactory as a liquid air trap, for preventing mercury vapour diffusing back into a vacuum system from a mercury pump. This method offers several advantages, with one disadvantage: it is difficult to clean commercial alkali metals and to avoid the introduction of various impurities (for example, organic vapours, hydrogen, carbonic dioxide) in the vacuum system. However, there exists one method —the glass-electrolysis—which enables very clean sodium to be introduced into closed glass vessels. This elegant method can be easily applied to any normal glass or pyrex glass apparatus by providing the mercury trap with an incandescent cathode and immersing it partially in molten sodium salt. We have already used a similar method in the manufacture of photoelectric cells.[2]

Mr. Ansiau, of this University, is at present experimenting with this method; the results will be recorded later.

Dispersion of Sound in Several Gases, and its Relation to the Frequency of Molecular Collisions

MEASUREMENTS on carbon dioxide, carbon disulphide, sulphur dioxide, and ethylene show that the dispersion of sound in these gases is sensitive to pressure. In each case the dispersive region shifts to higher frequencies with increasing pressures or, conversely, the velocity of sound at a given frequency increases as the pressure is diminished until a constant value is attained. At 30° C. and 451,000 cycles sec.$^{-1}$, for example, the velocity of sound is constant in carbon dioxide below about 350 mm., in carbon disulphide below about 100 mm., and in ethylene below about 40 mm. The corresponding heat capacity ratios are 1·4 for carbon dioxide,[1] 1·4 for carbon disulphide, and nearly 1·33 for ethylene; thus in each case only translational and rotational terms continue to participate in the sound wave under these conditions. In sulphur dioxide at 200 mm. the dispersion between 94 and 451 k.c. is only about 1·2 m. sec.$^{-1}$ at 30° C., indicating that frequencies above the present experimental range are necessary to demonstrate by the acoustical method that sulphur dioxide is not a linear molecule.

The temperature dependence of the dispersion of sound in carbon dioxide and carbon disulphide has also been studied. In carbon dioxide at 770 mm. the difference between the velocity of sound at 92 and at 9 k.c. is negligible at 60° C., whereas at 10° C. it is about 5·0 m. sec.$^{-1}$. Similar behaviour is manifest in carbon disulphide at about 320 mm.

The dispersion of sound in binary mixtures of ethylene with argon and nitrogen is exactly that calculated from pure ethylene at a corresponding partial pressure. It is concluded from this that the vibrational energy of ethylene is not excited by collisions with molecules of these gases. In hydrogen-ethylene mixtures, on the other hand, the effective heat capacity of ethylene rises sharply on the introduction of small quantities of hydrogen, and it is necessary to suppose that a collision with a hydrogen molecule is about ten times as likely to excite ethylene as a collision with another ethylene molecule. The analogy of this result to recent chemical evidence on the decomposition rates of the ethers is striking.

Because air, nitrogen, argon, propane, and pentane appear to be without dispersion (+0·2 m. sec.$^{-1}$) between 9 and 451 k.c. in the same apparatus it is believed that the measurements reported above are free from serious errors due to tube effects.

A quantitative description of the dependence of the dispersion of sound on pressure, temperature, and frequency has been obtained by incorporating in the dispersion theory of Einstein[2] the suggestions of Herzfeld and Rice[3] and of Heil[4]. If it is supposed that equilibrium between translational and internal energies is incomplete in high-frequency sound waves (H and R) and that only molecules of exceptionally high translational energy can excite molecular vibrations (H), an expression results which closely resembles that given by Einstein (and consequently that of Kneser[5] but which involves two additional constants. The first may be called the collision energy, and determines the temperature coefficient of the dispersion of sound much as the activation energy determines that of a chemical reaction rate. The second is dimensionless, and represents the fraction of collisions possessing the collision energy which result in vibrational excitation. For carbon dioxide these quantities are respectively about 4×10^{-13} ergs and 0·01. These magnitudes may be understood when it is remembered (Heil) that on collision less than half of the translational energy may be converted into vibrations, and that the type of collision necessary to excite a transverse vibration must be directionally extremely specific.

It is possible that a small potential energy wall may also impede the energy transfer. The two constants cannot be separated without assumption if more than one vibrational state of the molecule contributes to its heat capacity. Under these conditions a fine-structure should appear in the absorption band or, conversely, points of inflection should be manifest in the dispersion. These may be studied at constant frequency by lowering the temperature or pressure in the dispersive region.

Spectrum of Trebly Ionised Lead

THE spectrum of trebly ionised lead, which has been studied by several authors ending with S. Smith[1], requires modification in several respects. I have shown that $7p\,^2P - 7d\,^2D$ is really $7p\,^2P - 8s\,^2S$ and confirmed this by obtaining further combinations with the $8s\,^2S$ term. This provides a series of ^2S terms the values of which can be accurately calculated by Hicks's formula. $6s\,^2S$ comes out equal to 340180, giving an ionisation potential of 41·9 volts.

Structure of Line Spectra in Crystals

NEW investigations of the spectra of chromium in crystals[1] have rendered very probable the surmise expressed by Saha[2] as to how these spectra originate. The possibility is thus afforded of enlarging the explanation proposed previously[3] resulting in the main characteristics for a transition of an ing spectra of absorption determined by J. Becquerel, as I gather from a discussion with Mr. Gorter, of Harlem. The temperature behaviour of the lines is as expected (strong dependence on temperature of $^3F-^3H$ in relation to $^1G-^3H$ in praseodymium). Also the appearance of the transitions leading to the deepest level in absorption is fulfilled. As regards the intensities of the single lines, the transitions

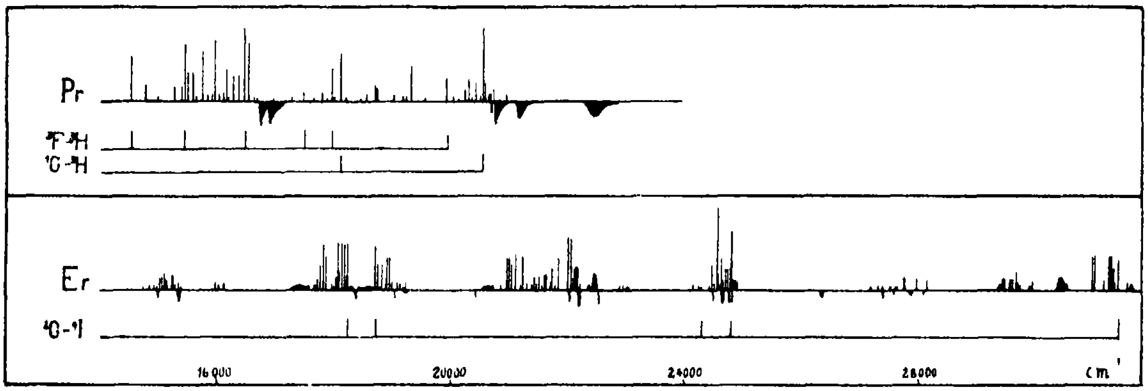

FIG. 1.

electron and its change through the crystal lattice, inasmuch as now also the laws of the various transitions of electrons for the spectra of phosphorescence of the rare earths can be investigated. The explanation of transitions $4f^{z} \rightarrow 4f^{z-1}\,5d$ offered by Laporte[4] should come into consideration only for the diffuse spectra of the rare earths, for example, of neodymium (also of samarium[5]).

In analogy with chromium we might attribute the sharp spectra to transitions without change of the electronic configurations. Then the principal transitions of electrons appearing in the respective spectra must be attributed to the multiplets produced by the combination of the possible terms of the unchanged electronic configurations. The separation of these terms has been calculated according to a method indicated by Goudsmit[6], and the single term intervals have been fixed according to the Landé interval rule. A very good concordance of the values calculated with the strongest lines of the emission spectrum, for example, in CaO, becomes manifest, as shown by Fig. 1 with the example of praseodymium and erbium, the values of which are indicated according to my own investigations and those of Evert and Fagerberg. The remaining lines originate in accordance with the former explanation partly from lattice oscillations and perhaps also molecular oscillations, partly also from Stark effects.

As these lengthy calculations of the splitting of the terms have not yet been carried out for all electron arrangements, the following combinations have been found up to now:

Pr: $^3F-^3H$, $^1G-^3H$, $(^1S-^3P)$
Nd: $^2I-^4I$, $^2G-^4I$
Sm: $^4F-^6H$
Er: $^2G-^4I$, $(^2K-^4I)$

The transitions without change of the spin are situated at longer waves than the corresponding ones with change of the spin. The screening constants are $\sigma_2 = 33 \cdot 0 \pm 0 \cdot 2$ for praseodymium, neodymium, samarium and erbium without appreciable direction of the different values.

The possibility of such transitions corresponds very well to the oscillator strength of the correspond-

$\Delta J = \Delta L$ are, so far as it is possible to judge qualitatively, mostly the strongest, even when $\Delta J = \Delta L = \pm 2$.

Anomalous Behaviour of Methane in the Raman Effect

DICKINSON, Dillon and Rasetti,[1] who examined the Raman spectrum of methane, did not report the presence in it of any pure rotational lines accompanying the Rayleigh scattering. To decide whether indeed the rotational scattering is absent in the case of this gas, spectrograms were obtained by giving prolonged exposures up to a week, but without recording even a trace of such scattering by way of either discrete lines or unresolved bands alongside the undisplaced lines of the mercury spectrum. Special devices for eliminating stray light and weakening the Rayleigh scattering with the aid of a nicol were employed in order to secure the most favourable conditions for the observation, but these made no difference to the result stated.

The absence of a rotational scattering, which is thus indicated in the case of methane, is an extremely surprising result, as it is well known that the Rayleigh scattering by the molecules of this gas is depolarised to an appreciable extent[2] (1·14 per cent), and theory indicates a direct connexion between the magnitude of such depolarisation and the intensity of the rotational Raman lines. Moreover, gases such as hydrogen chloride, ammonia, and carbon monoxide which show comparable or even smaller depolarisation values have been observed to exhibit strong rotational scattering.

Fixation of Mitochondria

THE importance of always omitting lipide solvents from fixatives for mitochondria has, I think, been exaggerated. I find that mitochondria are readily demonstrable in the liver of the newt and the kidney of the mouse even after fixation with Carnoy's alcohol-chloroform-acetic, which should certainly remove all lipides. Bouin's fluid preserves the mitochondria in the liver of the newt as well as the standard mitochondrial fixatives. When in Dalmatia in the summer I put the testes of some Hemiptera (*Syromastes marginatus*) into Bouin's fluid and left them in it until my return to England. On sectioning them I found the filamentous mitochondria of the primary spermatocytes well preserved.

Although mitochondria are in certain cases preserved by these methods, they are not thereby mordanted for subsequent staining. It is best to bring the sections to water and then leave them overnight in three per cent potassium dichromate in a paraffin oven. Next morning they are washed in running water for five minutes, and then stained by Altmann's technique or one of its modifications.

Champy[2] mentioned in 1911 that mitochondria are sometimes preserved by Bouin's fluid, and Romeis[3] in 1913 saw them, somewhat distorted, after Carnoy's fluid without chloroform. It seems that when there is a large protein component in mitochondria, there is no necessity to omit acetic acid and lipide solvents from fixatives used to show them.

I wish to retract my recently published remarks[1] on the fixative action of quinone. I placed tissues in quinone solutions and then transferred them to Carnoy's fluid. Mitochondria were not dissolved. In view of the current opinion regarding the action of Carnoy's fluid on mitochondria, I concluded that quinone was a powerful fixative for them. It is now clear that the evidence for this conclusion was insufficient.

Factors Determining the Distribution of *Apion ulicis*

IN connexion with the noxious weed control investigations at Farnham Royal Laboratory on behalf of the New Zealand Government, an experiment has been carried out in order to throw light upon the nature of the factors limiting the distribution of *Apion ulicis*; for this weevil is not found throughout the areas occupied by its host plant, *Ulex europæus*. Its abundance on the Moray coast, for example, and its absence from the Aberdeen district suggest the possibility that climatic factors in the north may only be suitable in the warmer districts.

The experiment consisted of the introduction of 25,500 mature insects, beaten off bushes, to an island in the River Don near its mouth at Bridge of Don, Aberdeen. This island is several acres in extent and has many large clumps of gorse upon it. Careful search was made previously to ascertain that no *Apion ulicis* was there. In November 1929, 500 Apions, collected from Nairn, were liberated; in January 1930, 5,000 from Buckinghamshire were liberated, and in April 1930 Dr. Guy Morrison liberated 20,000 from Buckinghamshire after making another search on the island for *Apion* and finding none. The gorse was in full bloom at the time of this last liberation. In April 1931 half an hour's beating of the bushes resulted in the finding of 15 live specimens of *Apion*, so that a considerable number must have survived the winter. In August 1932 another search was made and although only one dead *Apion* was beaten off the bushes, there were well developed *Apion* larvæ in four pods out of 300 examined, the total number of pods present being probably 1–200,000. Thus there is evidence that both winters must have been survived by many of the weevils and that normal breeding had taken place this year and probably last year also.

It may be, then, that the limited distribution of *Apion ulicis* is attributable to inadequate dispersal, but observations over a longer period are necessary before it can be definitely attributed to this cause rather than to the occurrence of occasional devastating conditions, such as long-continued low temperatures during the breeding season.

Undeciphered Scripts

REFERRING to the note in NATURE of October 1, p. 502, on the similarity of ancient scripts found in the Indus Valley and in Easter Island, it may be mentioned that Prof. Herman Wirth, of Marburg, has also directed attention to a number of similar symbols that have been found in North and South America, Sweden, Southern Andalusia, Mesopotamia, Africa and Oceania. He explains some of these signs on the usual lines of literal interpretation; but the fact that so many ideographs, "even [!] the *Svastica*" as Sir Denison Ross observes, are found in diverse parts of the world suggests that a certain class of archaic symbol cannot be interpreted as mere pictographs of material objects and local events. They obviously constitute the elements of a universal 'language' the symbols of which represent functions of Nature. The practical scientific knowledge of prehistoric civilisations implies some familiarity with the operations of the dual, positive and negative principle in Nature.

The knowledge of the physicist and biologist, hitherto neglected in palæographical research, may be required for the interpretation of some of these undeciphered 'scripts'. The geometrical and algebraical 'functions' of stresses, strains, and transformations of 'lines of force', do not vary from age to age; and, although the symbols for these in one era may seem abitrary to the savants of another age, the man of science is much more likely to find the 'key' than the man of letters.

Research Items

Stone Circles in Tongareva.—In an account of the ethnology of Tongareva, commonly known as Penrhyn Island (Bull. 92, Bernice P. Bishop Museum, Honolulu), by Te Rangi Hiroa (Dr. P. H. Buck), reference is made to two roughly circular arrangements of limestone pillars. Nothing is known of their uses and no name is applied to them by the islanders. It has been stated that stone circles of a Stonehenge type are present in Tongareva—an erroneous interpretation of the word 'encircled' used by Lamont loosely in describing a marae which in reality was rectangular. The stones are not to be ascribed to an archaic civilisation; they are of the same type as those used in marae construction, and sun worship was unknown to the Tongarevans. The pillars, including the bilateral notched pillar of the Atutahi ellipse, are trimmed in the same way as the marae pillars. They must have been made by the ancestors of the present population. They are in fact extra-marae pillars set up near the marae for some subsidiary purpose which, it is suggested, were social gathering places on the way to or from the marae. Women and children were not allowed to enter the marae. The secular use of the circle may be borne out by the discovery of a partly worked shell fish-hook in one enclosure. The circle may have been used as the place in which was performed the dance and the wailing ceremony, an accessory performance outside the marae that required a clear space not far away. The circle probably arose from a desire to embellish the clear space where such dances were held. In function it would be subsidiary and complementary to the marae and not taboo.

Cherokee Medicine.—The late James Mooney left unfinished a study of a manuscript of Cherokee sacred formulæ and medicinal prescriptions, which has been completed, edited and checked in the field by Dr. Franz M. Olbrechts and is published as Bulletin 99 of the Bureau of American Ethnology. The Cherokee original has disappeared. While the Cherokee recognise that natural causes, much as the fall of a branch of a tree, may bring about an injury, they may still explain it as due to the machinations of an enemy, while disease in general is attributed to the action of spirits, anthropomorphic or zoomorphic, out of revenge fo. a slight. A rival spirit will then be called in to drive the attacking spirit away. Spirits cause disease not only of their own volition, but also by being invoked by witches or a man-killer. Such spirits are the sun, the moon, the river, which is the central object of an important cult, thunder (more of a disease expeller than a cause of disease), the two sons of thunder, known as the two Little Red Men, the Purple Man, the Blue Man, the Black Man, etc., and the Little People, who act in groups rather than individually. The animal spirits are prototypes of the common animals, but exceed them in their qualities. To these must be added human and animal ghosts. Dreams may also cause definite ailments. Cherokee medical art does not aim at curing disease or allaying pain, but at removing the cause, which it is the first duty of the medicine man to ascertain, in the first place by interrogating the patient as to whether he has infringed any taboos or has had any dreams. Great as is the number of spirits causing disease, the number of those who drive it away is even greater. If a disease is thought to be caused by worms, worm-eating bird spirits will be called in. If the disease is of a very tenacious nature, the spirits of rats, beavers or weasels will be called in, because they also are tenacious and will gnaw and tear the disease-causing spirits.

Californian Shrimp Industry.—In the Fish Bulletin No. 38 of the Division of Fish and Game of California, Bureau of Commercial Fisheries, 1932, Mr. Paul Bonnot deals with the Californian shrimp industry in San Francisco Bay, both historically and statistically. Three shrimps make up the commercial catch, all species of *Crago*: *C. franciscorum*, *C. nigricauda* and *C. nigromaculata* in order of their abundance. These are all large animals measuring 2½–3 in. in length. Their life history is little known. Eggs may be found attached to the females throughout the year at various stages of development but there are no records of young shrimps being taken in the catches. Presumably they pass through the nets. Besides shrimps, *Pandalus danæ*, *Spirontocaris cristata* and *Upogebia pugettensis* are occasionally taken and large numbers of *Euphausia pacifica*, with numerous fishes of many varieties. The Chinese shrimp net and the shrimp trawl are both used and appear to be equally efficacious as the amounts of the catches from each differ little. The shrimps are for the most part boiled and put into barrels to be sent away to the dried shrimp market in China. The catches have greatly increased in the last fifteen years, rising from 200,000 lb. in 1915 to 3,000,000 lb. in 1929. The largest numbers were in July to October. Sun-dried shrimps lose three-fifths of their weight in the process. The dried material yields one-third shrimp meats and two-thirds shrimp meal by weight.

The Peritoneal Melanophores of Fishes.—The dermal chromatophores of fishes have been much studied but relatively little is known of the internal chromatophores present in the peritoneum, the pericardium, the walls of the larger blood vessels, the membranous coats of the central nervous system and elsewhere. In common cyprinoid fishes two kinds of peritoneal chromatophores are present, namely, melanophores and guanophores (or iridocytes) but there are no xanthophores. In the small Japanese species of minnow, *Acheilognathus intermedia*, selected for study by K. Yamamoto (*Mem. Coll. Sci.*, Kyoto Imp. Univ., Ser. B, vol. 7, No. 4, Art. 9, 1931) internal melanophores are plentiful; each is a minute stellate cell with numerous peripheral processes rich in dark brown or black pigment. It differs in shape from the dermal melanophore, for the latter has longer peripheral processes, and in distribution, for the peritoneal melanophores are more densely crowded so that they more readily join to form a continuous black screen. A single large peritoneal melanophore is surrounded by ten to thirty smaller ones all of which react together in expansion or in contraction. The dermal melanophore expands when the fish is kept in the dark and contracts when the fish is kept in the light; the peritoneal melanophore reacts in the opposite manner. Damage to the brain does not change the reaction of the peritoneal melanophore. In general the reaction time of this melanophore is slower than that of the dermal.

Hybrids of the Grass *Phalaris*.—Crosses have been made between *Phalaris arundinacea*, a grass of wide distribution in the northern hemisphere, and *Ph. tuberosa*, a Mediterranean species (T. J. Jenkin and B. L. Sethi, *J. Genetics*, vol. 26, No. 1). More seeds and a higher percentage of germination are obtained when *Ph. arundinacea* is the female parent. Both species are found to have $2n=28$ chromosomes, and hence are tetraploid, but in the hybrid meiosis 12 pairs of chromosomes are formed and 4 univalents. In both parent species there are 14 pairs of chromosomes in meiosis, but one or two bivalents may lag on the heterotypic spindle. The hybrids are functionally male-sterile, but a few good pollen grains are probably produced. They are vigorous and set seed freely in proximity to the parent species. Later generations showed considerable variability. On the basis of these results the theory of the hybrid origin of the Australian Toowoomba canary grass, which is also variable, is revived. It is suggested that this form, the status of which has been disputed, resulted from natural crosses in Australia between the introduced species, followed by back-crossing to *Ph. tuberosa*. It cannot be proved, however, that *Ph. arundinacea* was growing in Toowoomba at the time these crosses are supposed to have arisen.

Kimberlite in Tanganyika Territory.—The Shinyanga diamond fields have already been described by Dr. E. O. Teale in Short Paper No. 9 of the Geological Survey of Tanganyika Territory. Kimberlite occurrences have more recently been discovered on the Iramba Plateau, south-east of the former area, and these are now described in Short Paper No. 10, also by Dr. Teale. At Kisiriri the kimberlite occurs in sheet-like intrusions penetrating the granite along flat-lying joint planes; most of the sheets have chilled margins, the thickness ranging from thirty feet down to mere threads. At Kiomboi an irregular elliptical pipe occurs and other occurrences of kimberlite that probably lie over pipes are known in the Songeli and Mtawira districts. In some of these areas pitting and washing have been carried out, both on superficial gravels and on weathered kimberlite, but so far without encouragement except in the Songeli region, where two diamonds are reported from the river gravels. All the typical minerals such as ilmenite, garnet, olivine, diopside and zircon are found, and the Kiomboi pipe contains eclogite and numerous blocks of sandstone like that of the Upper Karroo. No outcrop of the latter is now present in the vicinity and the inclusions must have fallen in from a former capping of the formation.

Room Comfort.—It is now nearly twenty years since Sir Leonard Hill introduced the cooling of a thermometer bulb at body temperature as an indicator of the comfort of a room. The smallness of the instrument has been found disadvantageous and a committee of the Medical Research Council and of the Department of Scientific and Industrial Research has adopted a comfort-measuring device which was described briefly by Mr. A. F. Dufton of the Building Research Station in the *Philosophical Magazine* for May 1930 and is now described in detail by him in Technical Paper No. 13 of the Building Research Board entitled, "The Equivalent Temperature of a Room and its Measurement". It consists of a cylindrical vessel of thin copper painted black, 56 cm. high and 19 cm. in diameter, the temperature of which is maintained at 75° F. by a bi-metallic thermostat and a relay mercury switch which control the electric current through two electric lamps in the vessel, on a 200-volt circuit. A portion of the current flows through a coil which heats a thermometer, or a thermo-junction if a continuous galvanometer record is required. The indications of the instrument are thus proportional to the excess of 75° F. above a temperature for which the term 'equivalent temperature of the room' is proposed. The device is to be called a 'eupatheoscope'.

Polarity of Thunderclouds.—Experiments have been made in South Africa (E. C. Halliday, *Proc. Roy. Soc.*, October) to investigate the structure of thunderclouds by studying the changes in the atmospheric potential gradient accompanying different types of flash. The capillary electrometer invented by C. T. R. Wilson for such work was used, and an observer wrote notes on the flashes, at the same time marking the electrometer record. In some cases photographs of the flashes were taken. In 283 cloud-to-ground flashes, nearly all were accompanied by positive charges of the electric field. When the flashes took place within clouds, they usually produced negative field charges when distant and positive field charges when near. These results are consistent with Wilson's view that thunderclouds are charged positively above and negatively below. A number of simultaneous earth-cloud and within-cloud flashes were also observed.

Experiments with High-Speed Protons.—Chr. Gerthsen describes in *Die Naturwissenschaften* for September 30 an ingenious method for multiplying the energy of hydrogen positive ions. The ions are accelerated *in vacuo* and passed through a chamber filled with hydrogen where a process of exchange of charge takes place and fast neutral hydrogen atoms are produced. The neutral particles pass through a region of reversed potential into a second exchange chamber where fast positive ions are produced and these are accelerated by a potential derived from the same source as before. The arrangement tried gave proton currents of 10^{-8} amp. at velocities corresponding to 2×70 kilovolts, and the experiments of Cockcroft and Walton on lithium disintegration were repeated. The repeated application of the process is hindered only by intensity considerations, particularly as the probability of exchange of charge decreases with increasing particle velocity.

Sub-boundary Structures in Metals.—Deeply etched iron not infrequently shows within the crystals of ferrite a network the nature of which has been very obscure. Hitherto the general explanation has been that such sub-boundary structures were evidence of minute crystals the orientations of which varied very slightly. Similar effects have been noted in cast nickel and copper. In a paper to the Iron and Steel Institute (September, 1932), L. Northcott advances the view, which is supported by considerable experimental evidence, that oxygen in the metal is the cause. Iron which had not previously shown this structure did so when heated in contact with iron oxide, while a veined structure was removed by annealing in hydrogen within a certain range of temperature. The two other metals mentioned gave similar results.

Atomic Weights of Selenium and Tellurium.—The values obtained by Aston by the mass-spectrum method in the case of selenium and tellurium differ appreciably from those adopted in the International Tables of Atomic Weights. A revision of the chemical determinations has been carried out by Hönigschmid, who reports in *Die Naturwissenschaften* (1932, p. 659) that the analysis of silver selenide gives Se = 78·962 ± 0·002, coinciding with Aston's result, whilst the analysis of $TeBr_4$ gives Te = 127·587 ± 0·019, differing by 0·4 from Aston's value but agreeing with the International value and with a combination of Aston's results with the more recent mass-spectrum experiments of Bainbridge (*Phys. Rev.*, 1021, 1932), which disclosed some new lighter isotopes. A combination of the two spectra gave Te = 127·58 ± 0·15, in correspondence with the chemical value.

Mechanism of Flame Movement.—In the *Journal of the Chemical Society* for July, 1932, Coward and Hartwell, of the Safety in Mines Research Laboratories, describe experiments on the uniform movement of flame in mixtures of methane and air, with particular reference to the effect of the diameter of the tube on the rate of propagation. They confirm the fact that the speed of flame increases with increase in tube diameter; in a tube of 100 cm. diameter, a 10 per cent methane – air mixture would be propagated at about 250 cm./sec., whereas in one of 2·5 cm. diameter at only about 65 cm./sec. For tubes between 10 cm. and 20 cm. in diameter, there appears to be an inflection in the curves representing the speed. The authors explain this by reference to the nodular appearance of the flame, which is due to convection in the flame front, and does not occur in tubes of small diameter. The enlargement of the flame surface increases the mass of the gas burnt in unit time, and the speed of flame increases accordingly. Even in the case of downward propagation of flame in wide tubes, these irregularities in the flame front are visible, and the authors plead that 'uniform movement' of flame may be regarded as an early phase of sensibly uniform speed usually observed in the propagation of flame (through a quiescent gaseous mixture) from the open end of a straight tube towards the closed end, but not as resulting from a particular mode of heat transference, representing the normal speed of propagation of flame by conduction of heat.

Astronomical Topics

The Leonid Meteors.—A Science Service Bulletin, by James Stokley, points out that even people who have no astronomical training can do useful work in observing the Leonid meteors. It will help to determine the time of maximum if they count the numbers seen during each hour of the night. If the meteors are too numerous for all to be counted, the count may be limited to a definite region of the sky, bounded by known stars, which should be noted in making a report; a region should be chosen that will remain in sight throughout the watch. An alternative study is that of the brightness of the meteors. The planets Jupiter and Mars, and the star Regulus will be suitable for comparison. Each observer should limit himself to some definite field of work. The most probable nights are those between November 15 and 16, and between November 16 and 17. The moon will prevent observation of faint meteors, but there should be many bright enough to be seen.

The observatories of Kodaikanal and Helwan have been asked to telegraph to the B.B.C. if they see a rich shower, so there is a possibility of receiving warning before the radiant point rises (a little before 11 P.M.). As the rich portion of the shower takes about four hours to be crossed by the earth, it is more or less an even chance that some portion of the rich shower may occur in the interval between 11 P.M. and sunrise. In 1866 the nodes of Tempel's comet and the meteors were practically identical (231° 26′ comet, 231° 28′ meteors). The calculations of the B.A.A. Computing Section give 233° 54′ for the comet's node this year; if we assume the same for the meteors, the maximum would be about noon on November 16. The most hopeful time appears to be just before dawn on November 16. The sun rises at 7^h 19^m in London.

A Perplexing Variable Star.—The variability of the star R Scuti was discovered by Piggott in 1795, but the law of its variation defied analysis for more than a century. A special study of the star during the period 1911–1931 has been carried on at the Observatory of the University of Michigan, first under Dr. R. H. Curtiss, and after his death by Mr. D. B. McLaughlin. The results are contained in *Publications* of the Observatory, vol. 9, Nos. 9 and 10. It may be described roughly as of the β Lyrae type, with two unequal minima, the average length of the double cycle being 143 days; on the average the B minima occur 62 days later than the A minima. The brightness at maximum is fairly constant at mag. 5 or slightly fainter; that at minimum is very irregular. Sometimes it does not fall below mag. 6, while early in 1925 it fell below mag. 8. The most curious feature is that sometimes the A minimum, sometimes the B minimum, is the deepest; there is a suggestion that these disturbances of sequence occur at intervals of nine cycles, or about 1300 days. The 143-day period is also subject to cyclic variations. The paper does not attempt to give any physical explanation of the star's curious behaviour.

Total Solar Eclipse Observations.—It was mentioned as a 'novel resource' in a paragraph in the columns of "Astronomical Topics" in NATURE of October 1 on the total solar eclipse of August 31, that some parties of observers had dashed by motor cars to places where the clouds were less dense. Dr. Elihu Thomson, director of the Thomson Research Laboratory, General Electric Company, Lynn, Mass., writes: "In observing the eclipse of June 6, 1918, in Colorado, U.S.A., I secured an automobile for the very purpose of following the blue sky, and after making two shifts, reached a high ridge under blue sky just three minutes before totality and had an excellent view in consequence. I believe this process was novel at the time and was referred to in the Harvard Observatory Annals. In the last eclipse, I, with friends accompanying me, repeated the same process and saw the total phase of the August 31st eclipse, which would otherwise have been missed."

The Origin of Igneous Rocks

A DISCUSSION on the origin of igneous rocks was held in Section C (Geology) of the British Association at York on September 7. The discussion was opened by Prof. Arthur Holmes, who sketched out a general scheme of petrogenesis in the light of our present knowledge concerning the geological history, structure and thermal condition of the earth's crust. In certain continental regions the sedimentary and granitic layers appear to be separated from a deeper 'basaltic' layer by one which is probably composed of both acid and basic materials. The 'basaltic' layer is itself composite, a tentative interpretation being that amphibolite (a potential source of oversaturated basalts) is succeeded in depth by more basic granulite (a potential source of undersaturated basalts). Beneath these layers peridotite probably comes into place, merging within a few tens of kilometres into the glassy state regarded as characteristic of the substratum. Given some such setting of materials, igneous activity could arise, either by the ascent into the crust of heat from the feebly radioactive substratum, or by the accumulation of heat in specially thickened belts of the more strongly radioactive crustal rocks. The latter process fails, however, to account for the flooding by plateau basalts of regions where the crust has been thinned by denudation, and also for the ascent of granitic magma *during* orogenesis instead of long afterwards. The hypothesis of refusion of the crustal layers by heat from the substratum, with successive production of peridotitic, basaltic and granitic magmas, therefore seems to be worthy of special consideration.

From the fact that the basaltic magmas of the Inner Pacific differentiate towards trachyte and fail to produce rhyolites and dacites, it is possible to infer that the latter could be developed in quantity only where pre-existing granitic material has been available for refusion. To test the validity of this inference, which is supported by many other lines of circumstantial evidence, Prof. Holmes suggested a method based on the generation of Ca^{41} from K^{41} and its accumulation during geological time. If a Tertiary granophyre or other acid rock had been produced by refusion of pre-existing granite, then its Ca^{41}/Ca ratio should be of the same order as that for, say, Lewisian granite-gneiss. If, on the other hand, the granophyre had been a differentiate from basaltic magma, the Ca^{41}/Ca ratio should be of the much lower order characteristic of basalt. Determinations of Ca^{41} by Dr. F. Allison, who has devised an extraordinarily sensitive magneto-optic method of isotope detection, are now in progress with the view of trying out the practicability of the proposed test.

Attention was directed to the results of much recent work supporting the view that in both kratogenic and orogenic regions many 'intermediate' rocks have been generated as a result, not of differentiation acting alone, but of differentiation superimposed upon (*a*) the hybridisation of granitic magma by relatively basic igneous, metamorphic and sedimentary rocks, or (*b*) the acidification of basic magma by sialic materials. Turning to the consideration of ultrabasic rocks, Prof. Holmes suggested that in addition to peridotites representing accumulations of early-formed crystals from basaltic magmas there are others that have been intruded as peridotite magmas. It was maintained that the conditions favourable to the refusion of crystal-accumulates from basaltic magma would also suffice to generate magma from the peridotite layer at the base of the crust. The genesis of felspar-free alkali-rocks can be plausibly explained by assuming a peridotitic parentage for these rocks. It is not denied, however, that in some of its local applications the 'limestone assimilation' hypothesis has many attractive features.

From each of the different types of parental magmas—acid, basic and ultrabasic—a wide variety of rock-types can be produced by additive and subtractive differentiation, by assimilation, by the mixing of, and reaction between, various products (lamprophyres ?) and by all these processes acting concomitantly. Further possibilities of variation are introduced by differential fusion, and Prof. Holmes pointed out that magmas generated under stress are likely to be of abnormal composition (spilitic ?) as compared with those due to passive refusion.

Prof. A. Brammall examined evidence for the syntectic origin (as opposed to 'pure-blooded' descent from primary basic magma) of saturated and oversaturated magmas, with special reference to quartz-monzonites, hornblende-biotite-syenites, diorites, granodiorites and granites. He endeavoured to liberate the general genetic problem from what he aptly termed "the tyranny of the silica percentage". By eliminating normative quartz from analytical data for igneous, metamorphic and sedimentary rocks and plotting the results in triangular diagrams, he focused attention on progressive variation in the ratios of (*a*) salic to femic constituents, and (*b*) Ab to Or + Cor, in a theoretical differentiation suite. From this standard trend of variation the rock-types mentioned appear to be markedly aberrant. Not only does such aberration, in itself, logically hint at contamination, but also the rock-types displaying it are those for which a syntectic origin has been frequently asserted on first principles and convincingly demonstrated by field and geochemical evidence. Moreover, the crustal rocks actually assimilated in particular cases are of the general composition predicable from the 'overlap' of composition-fields plotted. Both the basification of acid magma, and the converse process, may be regarded as comparatively simple cases of the kind to be expected. The analytical and graphic methods outlined may afford some lead in the difficult problem of assessing probabilities concerning the fact of assimilation, and the composition of material which may have been assimilated at inaccessible depths before the consolidation of coarse-grained and essentially homogeneous rocks.

Prof. Brammall urged the need for intensive geochemical work on country-rocks—directed, in particular, to the study of 'consanguinity' as a further and possibly decisive criterion. Citations included progress reports on (i) the basic sills intrusive into Cambrian Shales flanking the Malverns near Eastnor, by Mr. F. G. H. Blyth, and (ii) hornblende-gabbro intrusive into Malvernian Schists at Hollybush, by Miss A. E. Cook and Prof. A. Brammall.

Dr. G. W. Tyrrell discussed the nature, mode of occurrence, and origin of basaltic magmas. He regards the existence of two main types of basaltic magma as established: the oversaturated or tholeiitic, and the undersaturated or crinanitic. In relation to geological environment three groups can

be distinguished: (*a*) *flood-basalts* (mainly over-saturated); (*b*) *oceanic basalts* (largely undersaturated); (*c*) *cone-basalts*, including those of rift valleys, horsts and troughs (dominantly undersaturated and notably felspathoidal). It was pointed out that the oversaturated type of magma has appeared at infrequent intervals but in enormous volumes, and that its chemical composition, as represented by basalts and quartz-dolerites, has been remarkably constant in space and time. While deriving undersaturated magmas directly from the basaltic layer, Dr. Tyrrell suggested that the oversaturated type may have originated by selective fusion of the peridotite or 'stony-meteorite' zone underlying the basaltic layer.

Dr. A. K. Wells expanded the evidence favouring refusion of ultrabasic material, with special reference to the dunite pipes of the Bushveld Complex. He endorsed the opinion that these 'carrot-shaped' intrusions are magmatic infillings, but regards them as re-fused differentiation products from the noritic magma of the Complex. Slides were shown demonstrating that both chromitite and magnetite-rock (presumed to have been derived from the norite) have behaved as fluids towards the associated silicate rocks. This striking reversal of the usual relations makes it not unreasonable to postulate refusion of early segregations. In connexion with the origin of the alkali rocks, Dr. Wells regrets that most British petrologists seem loth to accept the 'limestone-assimilation' hypothesis. He thinks the chain of circumstantial evidence cited by Prof. Shand is sufficiently strong to carry conviction, and he deprecates any suggestion that ijolite cannot be derived from basaltic or granitic magma, on the ground that it unfairly rules out the 'limestone-assimilation' hypothesis altogether.

Prof. H. H. Read examined the quality of the field-evidence connected with petrogenic theories. The rapid changes in the fashionable theories are clearly due to imperfections of field-knowledge. Arguments based upon badly exposed igneous bodies, such as the alkaline mass of Loch Borolan and Cnoc na Sroine in Sutherland, are obviously of little value. If petrologists endeavoured to assess the quality of their field-evidence we should have a guide to the order of validity of their conclusions. In Prof. Read's opinion, the field-evidence for refusion and palingenesis is entirely inadequate. In the case of contamination and hybridisation, however, the presence of discontinuities, and the complex and variable nature of the products, make the field-evidence of great value; but even here, the application of knowledge gained in these obviously mixed rocks to the interpretation of rocks about which no such field-evidence is forthcoming should be made with caution. The most important testimony in favour of assimilation as a petrogenic process is that read from field-evidence.

Mr. S. I. Tomkeieff presented an interim report of an investigation carried out in collaboration with Mr. C. E. Marshall on the Tertiary dykes of north-east Ireland, with special reference to 130 dykes of the Mourne swarm. These included olivinic types, but a majority belonged to the oversaturated and 'intermediate' types (andesitic variolites, leidleites, innimorites, etc.). The 'intermediate' types invariably contain half-digested xenocrysts of felspar and quartz, while xenoliths of partially fused granitic rocks are generally abundant. The field and petrographic evidence was found to be in perfect agreement with the views expressed by Prof. Holmes as to the origin of the similar suite of andesitic tholeiites occurring in the north of England. Mr. Tomkeieff outlined the igneous history of the Mourne centre as a whole and showed that the details are those to be expected on the theory of successive refusion advocated by Prof. Holmes.

Mr. W. Campbell Smith, in commenting on the views expressed by the previous speakers, pointed out that, from the nature of the case, field evidence of palingenesis was not to be expected on anything more than a very limited scale. He is disposed to counsel caution in extending the explanation offered for the evolution of leucitic rocks to the still less tractable problems of the soda-rich rocks.

Dr. H. Jeffreys said that the origin of the crustal layers themselves had not been touched upon, though he contends that this is the fundamental problem. He considers that the granitic and basaltic layers probably represent the products of residual magmas left over from the crystallisation of the material of the Lower Layer, and suggested the possibility that the process may still be going on.

International Institute for Documentation

THE eleventh Conference of the International Institute for Documentation was held in the Bibliothek für Kunst und Technik, Frankfurt am Main, during the week which ended on September 3. Great credit is due to Dr. Walter Schürmeyer, Director of the Bibliothek, for the excellent manner in which the Conference was planned and carried out. It is of interest to note that this Conference was the first held under the Institute's new title of "Documentation", which at the Tenth Conference (of the "Institut International de Bibliographie", as it was then called), held at the Hague on August 24–29, 1931, was chosen as a more appropriate title, in view of modern developments in the collection and classification of the records of intellectual activities.

On the first day, members of the Conference were received by the mayor and municipal authorities of Frankfurt, and by the Rector of the University, in the historical Kaisersaal des Römers; after which, a public assembly was held in the town hall, when Dr. J. A. Prins, director of the Dutch Patent Office, delivered his presidential address. All papers presented at the Conference were issued in two bound volumes[1] to participants in advance. M. Paul Otlet, one of the founders of the Institute in Brussels, spoke on the history and fundamental principles of documentation, and Dr. Ehrenfried Pfeiffer[2] described the technical documentation service of the Verein deutscher Ingenieure in Berlin.

There was a short discussion of the joint paper, "Systematic Subject Indexes to Periodical Volumes" by Prof. A. F. C. Pollard and Dr. S. C. Bradford[3], in which is described the method of the subject-matter index to volume I (1931) of the *Power and Fuel Bulletin*,[4] a notable development of indexing practice.

In Great Britain, where an undecimalised and therefore troublesome system of measures and money is still patiently endured, one would least expect to find the decimal system extensively adopted in the classification of literature; but Dr. S. C. Bradford[5] quotes a list of 28 important British scientific

institutions which, even in the year 1930, had decimalised and thus simplified their documentation. The fundamental value of decimal classification lies in its mechanical simplicity, its universal application, and its 'pure' numerical symbolisation which overrides all language barriers and opens up wonderful possibilities of international co-operation. The enthusiasm of all who have adopted the system and proved its worth, shows it to be a vital factor in modern librarianship.[6]

Abbreviated editions of the "Classification Décimale Universelle, Table systématique complète" have appeared in German[7] and in Spanish,[8] and a Danish edition is now in preparation. All such editions will be faithful translations of the French, and will follow the German in respect of abbreviation. The "Index Alphabetique de la Classification Décimale", a comprehensive alphabetical subject-matter index to the whole of the decimal classification system, can now be obtained from the Institut International de Documentation, Palais Mondial, Bruxelles.

In the course of the Conference, an exhibition was set out in the Bibliothek für Kunst und Technik, to illustrate modern library equipment, such as visible file indexes, photostat apparatus, and the application of the 'Adrema' system in mechanical selective documentation, which has been adopted with considerable success in the Bibliothek der Technischen Hochschule, Berlin,[9] for example. The Adrema Co. has now worked out in detail a scheme for the direct mechanical selection of decimal references to six places (that is, up to 999,999 or a million classification sub-divisions[10]).

At the conclusion of the Conference, a dinner was held in the clubhouse of the Frankfurter Gesellschaft für Handel, Industrie und Wissenschaft, a feature of which was the decimalised menu card. This was the work of Dr. Julius Hanauer, who threatened that at the next Conference he would produce an international menu card of decimal numbers without words. It was provisionally decided that the next Conference of the Institute should be held in Paris next summer, in collaboration with the Institut International de Co-opération Intellectuelle.

Structure of Solid Bodies

AN important symposium on the elementary structure of solid bodies (chiefly non-metallic), at which many distinguished foreign savants participated, was held in Leningrad on September 13–18 at the physico-technical institute.

In an introductory paper, A. F. Joffe (Leningrad) discussed the permanent distortion of crystals and pointed out that structurally perfect crystals offer least resistance to distortion. W. L. Bragg (Manchester) described the results of X-ray analyses of substances of more complicated structure, such as silicates. V. Heitler (Göttingen-Moscow) dealt with a semi-classical theory of the homopolar valence forces. Mrs. M. Classen (Leningrad) described the measurement of the limit of elasticity in perfect crystals and indicated that non-metallic crystals show annealing effects similar to those of metals. J. Frenkel (Leningrad) analysed the concepts 'solid' and 'liquid', pointing out that many properties which used to be considered characteristic of solids are shared to some extent by liquids, and vice versa. Liquids, for example, have a measurable rigidity under high-frequency mechanical oscillations. B. K. Fredericks (Leningrad) discussed the 'swarm theory' of liquid crystals. J. D. Bernal (Cambridge) considered the rational classification of crystals according to the nature of the weakest bonds and the rotation of molecules or radicals present.

J. Errera (Brussels) spoke on the dielectric polarisation of solids, distinguishing between ionic polarisation due to high frequency in substances far from their melting point (sodium chloride), and dipole polarisation due to low frequencies in substances near their melting point (water). A. V. Kurtchatov (Leningrad) dealt with the dielectric properties of Rochelle salt and explained the occurrence of the upper Curie point by the Lorentz interaction of rotating dipoles. The nature of the lower Curie point remains obscure, some ascribing it to the 'freezing' of the dipoles and others to a depolarising action determined by the symmetry of the crystal. N. Achulov (Moscow) considered magneto-striction and explained the abnormal character of the mechanical properties of ferro-magnetic bodies in terms of electronic orientations under the influence of mechanical stresses. He gave, further, a new method for calculating the magnetic susceptibility in crystals. P. L. Kapitza (Cambridge) spoke on magneto-striction in non-ferromagnetic bodies (bismuth and others).

R. H. Fowler (Cambridge) presented a report on Wilson's theory of semi-conductors which attributes their electrical properties to the thermal excitation of a very few electrons into states of motion which enable them to move freely through the crystal. In contrast to metals, the electrical properties of semi-conductors are classical. E. Tamm (Moscow) read a paper on the peculiar 'surface-bound' electronic states in non-metallic crystals and another paper on the calculation of the work-function for metals; in this he showed that the work depends solely on the polarisation of the metal (though the notion of the corresponding 'image-force' is not valid). Finally, J. E. Mayer (Baltimore-Göttingen) dealt with new developments of Born's theory of ionic forces in crystals, based upon the wave-mechanical conception of interatomic forces, and on electrical polarisation.

In connexion with the above symposium, a discussion was held on Dirac's electrodynamic theory to which Fock (Leningrad), Podolsky (Pasadena-Kharkov) and Shubin (Sverdlovsk) made interesting contributions. Nuclear phenomena, especially the

analysis of atomic structure in terms of protons and neutrons, and the repercussion of those phenomena upon the law of conservation of energy, also came in for a fair amount of discussion. Fowler and Dirac (Cambridge), Tamm, Frenkel and others joined in this discussion; its general tone differed from that of the similar discussion which took place at the recent York meeting of the British Association in that the unexplained behaviour of the energy distribution in the β-ray emission of radioactive bodies did not appear to shake the confidence of the speakers in the utility of the postulate of the conservation of energy when applied to subatomic phenomena.

VICTOR COFMAN.

Iron-cored Coils for Radio Frequencies

FOR several years past iron-cored coils for oscillatory circuits have been used by telephone engineers at audio frequencies and at the low radio frequencies which are used in carrier current telephony. In order to reduce the losses which would accompany the use of iron at frequencies of the order of 50,000 cycles per second, the magnetic material was made up in the form of iron dust or filings embedded in a wax or cement in such a way that each particle of iron was insulated from its neighbours. In this way the eddy currents were very restricted in their paths, and the resulting iron losses were reduced to a minimum, so that the presence of the iron increased the inductance of the coil to a much greater extent than its resistance. When attempts were made to use such cores for coils required for higher radio frequencies, however, they were found to be a disadvantage, and the best design of coil for use in the medium broadcasting band of frequencies has been found to be a single-layer air-core solenoid of suitable proportions of length to diameter.

In the *Wireless World* of September 16 an announcement was made of the production in Germany of a new magnetic material named "Ferrocart", which may have a considerable influence on the design and construction of inductance coils for, at any rate, moderately high radio frequencies. Details as to the exact composition and the mode of manufacture of this material are not yet available, but paper laminations appear to be used to carry the dust core, and the result is a decided improvement upon the old form of core with iron particles. Also a considerable advantage is obtained from the fact that "Ferrocart" can be made up in the form of annular rings for use in the toroidal type of inductance coil. In this manner the air path of the magnetic field of the coil is reduced to a minimum; and since there is less external stray field, the screening of coils in a receiver or other piece of apparatus is rendered an easier problem. In the "Ferrocart" coil the inductance is obtained with considerably fewer turns than is necessary when an air core is used, so that it becomes possible to make the coils quite small while still retaining thick or multi-stranded wire to ensure low copper losses.

Later issues of the *Wireless World* have contained the results of comparison tests of typical air-core coils with two coils of the new type, the larger of which was enclosed in a screening box about 2 inches long and 2 inches in diameter. At frequencies corresponding to the medium broadcast band of wavelengths, each of the coils gave a considerably better performance than two typical commercial coils of greater dimensions, as used in modern broadcast receivers.

The better of the two "Ferrocart" coils was, indeed, only surpassed by an unusually well-designed air coil using stranded wire wound on a three-inch diameter former, containing two or three times the amount of copper wire and presenting considerable difficulty in screening it without loss of efficiency. It is understood that a firm has already arranged to develop the applications of "Ferrocart" in Great Britain.

Weather Charts of the Northern Hemisphere

THE Deutsche Seewarte, Hamburg, has undertaken to produce on behalf of the International Meteorological Organisation, daily synoptic weather charts covering the whole of the northern hemisphere. It is not intended to produce a synoptic chart differing from those published daily by the British Meteorological Office merely in the size of the area dealt with—the British charts cover only a small portion of the large area between the equator and the northern tropic—but one which shall contain the maximum possible amount of detail. For this purpose, it will be necessary to use more material than is provided by the ordinary international exchange of weather reports by wireless, and consequently these extended weather maps will not be available soon enough for direct use in daily short period weather forecasting. Their indirect value in forecasting may, on the other hand, be very great.

It is the view of many meteorologists that an understanding of the causes of long spells of abnormal weather can only be arrived at by the study of charts of this kind, a study which can be pursued at leisure, working on past weather situations. In the future such extended charts will be available in time for direct use in daily forecasting, but meanwhile the knowledge gained from the study of those now to be prepared should prove valuable in interpreting existing charts in much the same way that knowledge gained from a study of the synoptic weather charts of Europe and the North Atlantic solved some of the difficulties of forecasting from charts covering only a portion of Europe such as were used in most countries until recent years. But it is in the further development of long range forecasting that they are likely to be of the greatest utility. Seasonal forecasting of rainfall has been carried out with some measure of success in India and some other countries by means of equations derived from the theory of correlation, the future rainfall being correlated with various antecedent values of meteorological elements in distant countries. It is possible that the new charts may cause this method to be replaced by other more scientific methods based on a better understanding of the general circulation of the atmosphere.

It is hoped to begin the series with the period

of the International Polar Year 1932–33. In order that an idea of the probable number of purchasers may be gained, and that matters may be so arranged that the publication shall be developed into a permanent institution, the Deutsche Seewarte, Hamburg, would be glad to hear in advance from anyone who is likely to place orders for the new charts, and is prepared to submit sample charts and supply any information required. The cost of publication has to be covered by the sale of the charts, and the enterprise therefore depends for its success upon there being a sufficient number of purchasers to keep the price of the individual charts reasonably low.

University and Educational Intelligence

CAMBRIDGE.—Dr. H. R. Hulme, of Gonville and Caius College, has been elected to an Isaac Newton studentship, and W. E. Candler, of Trinity College, and R. H. Stoy, of Gonville and Caius College, have been elected to additional Isaac Newton studentships tenable for one year.

OXFORD.—The electors to the Hope professorship of zoology propose shortly to proceed to the election of a successor to Prof. E. B. Poulton, who has resigned as from January 1, 1933. The resignation of Prof. Poulton, who has held the chair for forty years in succession to the first Hope professor, the late J. O. Westwood, is greatly regretted. It is understood, however, that he intends still to carry on in the Hope Department those researches which have had such fruitful results, especially in the field of insect bionomics.

WALES.—It is stated in the annual report of the Council of University College, Swansea, that the capital deficit of the College has now been extinguished. There is urgent need for a new library, and the Council has decided to raise funds for the provision of a permanent building. It is proposed to issue private appeals for this purpose. The College has established a metallurgical research council to conduct investigations into problems which concern the chief industries of the region.

A STUDY of the place of physical education and hygiene in the curricula of teacher-training institutions has been published as Bulletin No. 10 of 1932 of the United States Office of Education. It is increasingly recognised that the effectiveness of teaching is dependent on the physical health of both teacher and taught, and in about half of the States teacher-training institutions are required by law to include physical education in their general curricula. In some of the States all applicants for teaching positions are required by the State boards of education to present credentials in physical education and health education. In West Virginia physical education is given a prominent place in all types of certificates granted by training colleges. The report directs attention to the fact that a successful programme of health education and physical education is not easily organised or measured in terms of clock hours of instruction or semester hours of credit and that nearly all training colleges provide opportunities for additional physical activities other than those prescribed, including 'hikes', week-end excursions and camping expeditions.

Calendar of Geographical Exploration

Nov. 13, 1876.—Doughty's Wanderings in Arabia

Charles M. Doughty started from Muzeyrib on his two years of wandering in Arabia. His "Arabia Deserta" has been described by D. G. Hogarth as the "Georgic of the Desert"; he characterised surely, sensitively and for all time the immemorial tribal life of the steppe and desert. He wandered as the poorest of the poor among the Bedawin tribes and faithfully and in minutest detail recorded their life and that of the oasis towns. He had been fired with ambition to visit Arabia when wandering in 1875 in the country beyond Jordan. Refusing even to pretend to forswear his faith, he openly travelled as a Christian and, though often persecuted, yet achieved his aim and attained the last station on the pilgrim route to Mecca. His unique journey resulted in contributions to geographical knowledge and to literature; it also gained for him a great reputation with Semitic scholars for the copies and drawings of the Nabathaean and Himyaritic scripts which he obtained.

Nov. 14, 1770.—Sources of the Blue Nile

James Bruce reached the source of the Blue Nile. In June 1768 he arrived at Alexandria, thence he visited Thebes and crossed the desert to Kosseir. He sailed to Jidda and after a stay in Arabia re-crossed the Red Sea, landed at Massawa and finally reached Gondar, the capital of Abyssinia. There his medical skill procured him the support of the Queen Mother, a very useful ally during his troubled stay in Abyssinia. On October 28, 1770, he left Gondar and, from the top of a gently rising hill on which was the church of St. Michael of Geesh, viewed the sources of the Blue Nile. On his return to Gondar political difficulties detained him until December 1771, but then he was allowed to return by Sennar to Nubia. In the Nubian Desert, sand storms and thirst so oppressed the party that the notes and observations of his journeys were discarded, though fortunately Bruce later recovered them. He reached Cairo in January 1773. Bruce was disappointed that the source of the Blue Nile was not considered, as he himself considered it to be, the real source of the Nile. Moreover, the source of the Blue Nile had been previously visited by the Jesuits. Thus the importance of his journey was rather that he re-discovered these regions and in so doing attracted the attention of his generation to African exploration. The five volumes in which he gave his experiences remain a vivid picture of travel in these regions and give much information about the geography, history and social customs of Abyssinia.

Nov. 14, 1805.—Finding a Route Across the Rockies

Capts. M. Lewis and W. Clarke reached the mouth of the Columbia River. They had left the Missouri in May 1804, wintered with the Mandan Indians, resumed the journey up the Missouri, crossed the Rockies and reached the Columbia River, where they wintered. In March 1806 the party divided, Lewis going via the Lolo Pass and thence carrying out certain explorations, while Clarke proceeded to the Yellowstone at its nearest approach to the three forks of the Missouri. They met again on the Missouri and reached St. Louis in September, 1806. The outward journey was calculated at 4134 miles, and Lewis's shorter return journey at 3555 miles from the mouth of the Missouri to the Pacific. They had been

commissioned to explore the Missouri from the point of view of the most direct and practicable water communications across the continent to the Pacific for commercial purposes. They achieved this object and also helped to attract traders to the regions west of the Mississipi by their accounts of possibilities of development.

Nov. 14, 1917.—Philby in Arabia

H. St. J. B. Philby arrived in the Gulf of Bahrain on a political mission to Riyadh, in the course of which he crossed the country from Ojair to Jedda, returned to Basra and once more set out to Riyadh. Thence he journeyed south to Wady Dawasir, thus penetrating some distance into the Nejd. In 1920–22, Philby crossed from Amman to Kabala near the Euphrates. With him went Major A. L. Holt, who had already made extensive surveys between Bagdad and Haifa. Philby's greatest Arabian exploit, however, was the crossing of the Rub' al Khali, the great waterless southern desert, in the early months of 1932. Starting from Hufuf on Jan. 7, he succeeded in reaching Sulaiyil, covering 1800 miles in 90 days. Finds of flint implements and freshwater shells indicated the site of an old riverbed or lake at Bir Maqran, and at Wabar craters of meteoritic origin were discovered. The first crossing of this desert, though by a different route, was in 1931, by Mr. Bertram Thomas.

Societies and Academies

LONDON

Royal Society, Nov. 3.—J. Mellanby: Secretin. Secretin may be prepared from the duodenal mucous membrane by (*a*) extraction with absolute alcohol, (*b*) precipitation by dilute acid, and (*c*) resolution of the precipitate in acid alcohol and precipitation by acetone. The product has the percentage composition of a sulphur-containing protein. It is soluble in water but insoluble in dilute acid. The physiological actions of secretin are: (*a*) the production of a copious secretion of pancreatic juice, (*b*) the contraction of intestinal muscle, and (*c*) the secretion of a small quantity of bile.—**Margaret Hill and A. S. Parkes:** Studies on the hypophysectomised ferret (1, 2, 3). Hypophysectomy of the male during the breeding season (June) caused regression to the anœstrous condition in about a month; the regression being characterised by decrease in testis weight and by aspermatogenesis. The experimentally produced degeneration is about three times as rapid as the normal decline into anœstrus. In the female ferret, removal of the pituitary body about two hours after the beginning of copulation did not inhibit ovulation, which occurs in the normal animal about 36 hours after mating. It would thus appear that some ovulation-producing substance is secreted by the anterior pituitary body within two hours of the beginning of copulation. The corpus luteum, however, failed to develop, and there were no signs of pregnancy or pseudo-pregnancy.—**J. D. Gillett and V. B. Wigglesworth:** The climbing organ of an insect, *Rhodnius prolixus* (Hemiptera; Reduviidæ). It is present in both sexes of the adult, but is absent in the nymphs. It occurs on the distal end of the tibia of the anterior and middle pairs of legs. It enables the insect to climb upwards on clean glass at almost a right angle, but it is of little use in the reverse direction. The organ is a little oval sac of pliant chitin filled with blood. On its lower surface it bears about 5000 tubular hairs, 1 μ in diameter, which appear to be the outlets of unicellular glands producing an oily secretion. At their free ends the anterior surface of these hairs is cut away obliquely so that only their hind margin comes in contact with the surface as the insect climbs. Among these hairs are about 50 delicate tapering hairs arising from large sockets and projecting slightly beyond the others. These appear to be sense organs. They are surmounted by a spindle-shaped mass of cells giving off a nerve fibre.

Physical Society, Nov. 4.—M. Fahmy: A further point of analogy between the equations of the quantum theory and Maxwell's equations. A previous paper (*Proc. Phys. Soc.*, 43, 124; 1931) dealt with an analogy between the electromagnetic equations in free space and the equations of the quantum theory, exhibited by means of five-dimensional geometry. In the present paper the analogy is pursued further and leads to the Eddington relation between the number of electrons in the universe and its radius.—**Lewis F. Richardson:** Time-marking a kathode-ray oscillogram. Time-marks have been arranged as little blurs or gaps in the trace, by periodically unfocusing the electron stream. The current in, and voltage across, a conductor can thus be recorded together with the time on a single oscillogram.—**T. C. Richards:** The elastic constants of rocks with seismic applications. The results of a geophysical survey by means of the seismic method over a large oil-bearing limestone structure in south-west Persia indicate that the limestone possesses a higher elastic velocity at its lower boundary than at its upper. Specimens of the limestone at different depths obtained by 'coring' do not give the same elastic constants when measured by a simple optical method, and the bearing this result has on the practical seismic observation is discussed.—**L. R. Wilberforce:** A common misapprehension of the theory of induced magnetism. It is usually stated that if any given magnet is immersed in a medium of permeability μ the magnetic field around it is similar to that in a vacuum, but diminished in strength in the ratio of $1 : \mu$. This statement is inconsistent with the ascertained experimental laws of induced magnetism.

PARIS

Academy of Sciences, Oct. 3 (195, 565–588).—Ernest Esclangon: The total eclipse of the sun of August 31, 1932, observed in the United States and in Canada. In spite of some cloud, good spectrographs of the corona were obtained, also some excellent general photographs of the corona.—**Lucien Daniel:** The experimental production of small bulbs in the leek.—**Claude Chevalley and André Weil:** An arithmetical theorem on algebraical curves.—**Nikola Obrechkoff:** A general method of summation of divergent series.—**D. Riabouchinski:** Some considerations on the hydrodynamical interpretation of the periodicity of sunspots. An account of experiments with a glass globe containing water, rotating on its axis and containing a stirrer rotating in the same direction, but faster than the globe. Some air was admitted to the globe and photographs are reproduced showing the internal movements. The theory of J. Wilsing on the constitution of the sun is discussed from the point of view of these experiments.—**Louis de Broglie:** Remarks on the magnetic moment and moment of rotation of the electron.—

J. Gilles: The intensities of the components of the hyperfine structure of the most intense lines of the visible spectrum Hg I. The hyperfine structure of the term (Hg 199)7^3D_2.—J. Durand and E. Raguin: The granite of the region of Pinet (Aveyron).—D. Montet: The action of radioactivity in plant physiology. The experimental conditions necessary to prevent confusion between the effects of catalysis and radioactivity are indicated. The use of a salt possessing manurial effects, such as a nitrate, should be avoided.—René Petit: The magnification of correcting glasses.—F. Vles and A. de Coulon: New experiments on the rôle of the electrostatic conditions in the appearance of spontaneous cancers in mice.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 18, 525–565, Aug. 15, 1932).—Lester S. King and Clyde E. Keeler: Absence of corpus callosum, a hereditary brain anomaly of the house mouse. Preliminary report. The character segregates sharply, is probably inherited as a unit character, is not sex-linked and is not due to the presence of the rod-less gene.—T. R. Hogness and R. Ruth Comroe: A search for evidence of the radioactive decomposition of barium. Working on the idea that barium might dissociate into xenon and helium, five rock specimens, all probably of Palæozoic age, were disintegrated and the residual gases examined. No xenon was found spectroscopically. By the method used, 10^{-7} c.c. or about 3×10^{12} atoms of xenon could have been detected. Hence it is calculated that, if barium is radioactive, its half-life period is not less than 10^{15}–10^{18} years.—W. H. Rodebush and W. C. Klingelhoefer: The reaction of chlorine with hydrogen. Atomic chlorine has been prepared and its reaction with hydrogen gas investigated at low temperature.—James H. Hibben: An investigation of intermediate compound formation by means of the Raman effect. Evidence was obtained for the formation of compounds in solution between aluminium chloride and ethyl alcohol, and zinc chloride and methyl alcohol, and for polymerisation of aluminium chloride in water.—Sylvia M. Mills: (1) Double innervation of melanophores. When an area on a specimen of *Fundulus heteroclitus* was denervated, a few of the melanophores which expand over a black background fail to contract over white. Response to electrical and mechanical stimulation also suggests double innervation.—(2) Neuro-humoral control of fish melanophores. The melanophores of a denervated region show a progressive lag, greatest at the centre of the region, in their responses to stimulation. Similar results were obtained with an isolated tail. It is suggested in explanation that melanophore nerves, when stimulated, produce a secretion causing melanophore contraction; this secretion is probably not carried in the blood system.—Arthur Bramley: Gamma radiation. A theoretical discussion using an oscillator which accounts for the needle-like character of the radiation field for very high frequencies.—Chester Stock: An Upper Oligocene mammalian fauna from southern California. The fauna of the Sespe beds of Kew Quarry, which occurs to the west of the Simi Valley, Ventura County, California, is more advanced than that from the Sespe beds north of the Simi Valley (NATURE, 130, 675, 1932). Its age is considered to be not later than Lower Miocene or earlier than Upper Oligocene.—A. D. Michal and J. L. Botsford: (1) An extension of the new Einstein geometry. Developments of the paper by Einstein and Mayer on "Unified Field Theory" (1931).—(2) Simultaneous differential invariants of an affine connexion and a general linear connexion.—S. S. Wilks: The standard error of a tetrad in samples from a normal population of independent variables. An exact expression is derived but it is said to lead to very complicated results.

Forthcoming Events

MONDAY, Nov. 14

UNIVERSITY OF LEEDS, at 5.15.—Prof. H. H. Swinnerton: "Fossil Clues and Hereditary Problems".

ROYAL GEOGRAPHICAL SOCIETY, at 5.—"Early Maps of Great Britain". E. Heawood: "The Tschudi Map"; Miss J. B. Mitchell: "The Matthew Paris Maps"; R. A. Pelham: "The Gough Map".

TUESDAY, Nov. 15

CHADWICK PUBLIC LECTURE, at 5.15—(at the Royal United Services Institution, Whitehall).—Sir Pendrill Varrier-Jones: "The Employment of Tuberculous Patients".

BRITISH INSTITUTE OF PHILOSOPHY, at 8.15—(at University College, Gower Street, W.C.1).—Sir Arthur Eddington: "Physics and Philosophy".

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. E. J. Garwood: "Kangchinjunga".

BRITISH PSYCHOLOGICAL SOCIETY, at 8.30.—A. H. Seymour: "The Borderland between Education and Industry".

WEDNESDAY, Nov. 16

BRITISH ACADEMY, at 5—(Annual Lecture on a Mastermind).—Prof. James Gibson: "Locke".

ROYAL METEOROLOGICAL SOCIETY, at 5.—J. Edmund Clark, I. D. Margary, R. Marshall and C. J. P. Cave, "Report on the Phenological Observations in the British Isles, December 1930 to November 1931".

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.30.—Discussion on "The Law of Priority in Nomenclature," to be opened by Prof. W. A. F. Balfour-Browne.

THURSDAY, Nov. 17

CHEMICAL SOCIETY, at 8.—Discussion on "Combustion of Gases in Electric Discharges", to be opened by Prof. G. Ingle Finch.

BEDFORD COLLEGE FOR WOMEN, at 5.15—(Stevenson Lecture).—Sir Josiah Stamp: "The Relation of Finance to Rationalisation".

UNIVERSITY COLLEGE, LONDON, at 5.30.—Sir Charles Sherrington: "Reflex Action" (succeeding lecture to be announced later).

FRIDAY, Nov. 18

ROYAL INSTITUTION, at 9.—Dr. R. G. Canti: "Cultivation of Living Tissue Cells".

Official Publications Received

GREAT BRITAIN AND IRELAND

Report for 1931 (No. 40) on the Lancashire Sea-Fisheries Laboratory at the University of Liverpool and the Annual Report of the Marine Biological Station (No. 45) at Port Erin, Isle of Man. Pylons and Pipelines

THE conspicuous network of high tension cables which is being spread criss-cross about the countryside may serve to remind us of the far greater ramifications of gas pipes and cables underground. Indeed, the streets of the cities of the world are as busy transporting material below the surface as above it, whilst in some lands, notably in America, pipelines carrying natural gas run across the countryside for great distances.

To-day there is increasing competition between gas, electricity and raw coal as sources of heat : all three use the product of the mine as their starting point. In the gas industry selected coals are carbonised so as to give a maximum yield of gas and a solid fuel—coke. In the electrical industry, low grade coal is burnt in highly efficient boiler plants and the steam produced converted in turbines into electrical energy. The domestic user of forty million tons of coal per annum burns specially large or lump coal mined for the purpose, the smalls, so-called slack, being burnt under industrial boilers. By means of pipes and cables, gas and electricity are carried directly into every room of the consumer's house ; he only has to turn a tap or pull a switch to obtain service from them : the advantage over coal is overwhelming. It is not necessary for him to keep stocks of either : there are no ashes to be removed by hand : they produce neither dirt within the house nor smoke without. On the other hand, coal has to be transported by train to the local depot, by cart to the house cellar, by hand in buckets to the room, and it is applied again by hand to the fire at irregular intervals. Gas fire and electric stove burn regularly and at constant efficiency : the coal fire burns with very variable efficiency.

For water heating, central heating, and similar purposes coal is replaced by coke, a product of the gas industry which, now that it is made under close supervision and delivered as a high-class material, low in ash and moisture content and regular as to size, has proved to be admirably adapted for the purpose : stoves fired with it require a minimum of attention. Such heating can also be done with gas or electricity, working under thermostatic control, the economics of the operation depending on their price.

A serious competitor of the three methods of heating based on coal is imported oil, firing by which is likewise automatic in its operation. Both for industrial boilers and for public and private

central heating, oil fuel is continually making headway.

The use of raw coal is in fact unscientific and 'unmodern': it also brings with it all the evils of the smoke nuisance, dirty and dismal cities, and consequent ill-health. Many would abolish it by legislation, yet somehow the coal fire survives, partly for psychological reasons, partly because of the capital cost of replacing it, and partly also because, to the man who burns it in anything like an efficient grate, it is still the cheapest source of heat.

Gas and electricity are still too dear in most parts of Great Britain, not because of any lack of technical efficiency, leading to high production costs in either industry, but to the high cost of all that is comprised under distribution charges. Although both industries are making progress, and must continue to do so as they are continually modernised, the price factor is still the determining one in their more general utilisation. Users economise with them and do not use them as freely as their value merits. With more reasonably priced fuel there would be far less parsimony and better health. By his invention of the steam turbine the late Sir Charles Parsons halved the cost of generating electricity: the cumulative inventions of this century in the gas industry have probably had nearly the same effect.

In the coal trade likewise the distribution costs are far too high: in no other basic commodity does the price at the source bear so small a proportion to the price delivered to the householder. Some day perhaps house to house deliveries by one firm only in a given street on a particular day will become obligatory, as it should be with the essential food services. We add enormously to the cost of living by neglecting such elementary economies.

The coal industry could do much to help the situation. Never was any policy more shortsighted than the decision taken when statutory coal prices were fixed, to mulct the gas and electricity companies in extra charges because they were able to pay the same. It is senseless to seek to establish permanence for a price from gas companies which is higher than that got from other users of precisely the same brand of coal. It would be far more to the interest of the mines to give minimum rates to these industries, with the certainty that at lower prices they could greatly increase their sales and hence their consumption of coal.

The fight between home coal and imported oil is becoming very acute: it is certain, for example, that another coal strike would nearly eliminate coal from factory boilers. The coal industry must realise that the day of raw coal, either on land or at sea, is passing and coal must largely be burnt in such a manner that the energy in it reaches the former customer in a more up-to-date form. The whole technique of mining requires re-examination from this point of view: it should generally be possible to mine a coal of the best size for a particular use, and not add to the mining costs by specially bringing large coal to the surface.

A dangerous competitor of the coal industry for the generation of electricity is water-power, though fortunately for the mines this is as yet but little developed in Britain. It has been calculated that in Europe the progressive expansion of water-power is annually displacing 5 million tons of coal, whereby annually 5000 miners become superfluous.

Fortunately again for the coal industry, we have practically no natural gas in Britain—this now substitutes 78 million tons of coal in the United States. Of the 100,000 miles of pipelines in that country 65,000 miles are used to convey natural gas, individual lines being upwards of 1000 miles in length.

There has developed very rapidly in the United States a use for the propane and butane fractions which can be scrubbed out of natural gas and are sold liquefied, either in cylinders or in pressure tank cars. Propane is used in individual farms and houses where towns gas is not available. The sales of the liquefied gas have increased at a very rapid rate: they were 18 million gallons in 1930 and 28 million gallons in 1931, and the number of customers served with propane was 117,000 in 1930, as compared with 55,000 in 1929 and 20,000 in 1928. The use of the butane fraction has developed along the lines of establishing central stations in communities too small to support a gas works. Butane is mixed with air, and the resulting mixture distributed and metered to residents in the settlement in the same way as towns gas. In this way the remote countryside has all the advantages of gas enjoyed by the dweller in the city and at a comparable price.

The development of the use of gas in cylinders has brought to the front again the question of gas as a motor fuel: in Britain important experiments are in progress to this end. On the test bench, the maximum power output of a standard low compression engine when running on towns gas as

compared with petrol is 88 per cent, and by either increasing the compression ratio or enriching the gas with benzol, it will be possible to raise the maximum power when running with gas almost to that obtainable with petrol. A test vehicle is being run on the road with special steel cylinders of light construction, containing gas at a pressure of 3000 lb. per square inch : these are well within the range of metallurgical technology, and their construction can no doubt be cheapened when the occasion arises. Even more progress in trying out gas has been made in France with satisfactory results.

Should these experiments be successful a new era in motoring would arise in Britain, with an equally great repercussion on the gas industry. The organisation of a chain of compressing and filling stations would not present any insuperable difficulties. In particular, the makers of gas of high calorific power would come into their own, as this would afford additional mileage without refilling, though probably some agreed standard gas would have to be furnished throughout the country, so as to avoid the necessity of adjusting the proportion of gas to air supply on engines of motor vehicles. Undoubtedly also, engines burning gas could be so designed as to give complete combustion, thus avoiding the large proportion of carbon monoxide which is at present produced from petrol.

The running of motor vehicles on gas made from British coal would have a profound effect on the gas industry, which with the increased make would be able to lower its price for gas to the householder. The railways, too, would once more have a large quantity of coal to transport. Surely the effort to solve this problem is worth making by all parties, including the mines. If, as at present, they continue to hold gas and electricity up to ransom, they are eventually doomed.

Equally useful to the mines would be the solution of the motor car fuel problem on quite other lines, for example, the discovery of a dry cell of large capacity which could be quickly recharged at local filling stations. Such an invention is by no means beyond the bounds of possibility.

Dr. A. E. Dunstan, in his brilliant summary of fluid fuels to-day and to-morrow delivered before the Society of Chemical Industry, considers that the coal era will be succeeded first by an oil era, then by a gas era, and finally by an electricity era, coal of course being the primary basis for the two latter. To-day coal is still responsible for seventy per cent of the power produced in the world. Great Britain has coal but no oil ; the use of oil to-day is outstripping that of coal. It will continue to increase as the Diesel engine is perfected, unless more coal is burned in the modern way.

We, at all events, must rush through the oil era and reach that of gas without delay. Let our pylons and pipelines be significant of the will to do this, otherwise tank farms will replace winding shafts on the landscape.

Large Molecules

Die hochmolekularen organischen Verbindungen—Kautschuk und Cellulose. Von Prof. Dr. Hermann Staudinger. Pp. xv + 540. (Berlin : Julius Springer, 1932.) 52 gold marks.

PROF. STAUDINGER'S book on "Large Organic Molecules" is based upon a series of sixty-nine papers on "Highly-polymerised Compounds" and thirty-nine papers on "Isoprene and Caoutchouc" which have been issued during the period 1920–26 from Zurich, and during the period 1926–32 from Freiburg, as a record of researches carried out under the inspiration and control of the author. No attempt has been made to cover the whole field, and in particular the large molecules of the proteins have not been considered. Nevertheless a very clear general idea emerges from the detailed experiments of which a summary is now given. The author is in fact a real organic chemist, who believes in real bonds, and is prepared to extend indefinitely the conception of homopolar molecules, in which *all the atoms are held together by normal covalences.* This idea follows logically from his observations on the progressive polymerisation of compounds such as :

(i) Polyoxymethylene,

$$CH_2O \longrightarrow -CH_2-O-(CH_2-O)_x-CH_2-O-$$

(ii) Polystyrol,

$$\overset{\overset{\displaystyle C_6H_5}{|}}{CH}{=}CH_2 \longrightarrow -\overset{\overset{\displaystyle C_6H_5}{|}}{CH}-CH_2-(\overset{\overset{\displaystyle C_6H_5}{|}}{CH}-CH_2)_x-\overset{\overset{\displaystyle C_6H_5}{|}}{CH}-CH_2-$$

(iii) Polyvinylalcohol,

$$\overset{\overset{\displaystyle OH}{|}}{CH}{=}CH_2 \longrightarrow -\overset{\overset{\displaystyle OH}{|}}{CH}-CH_2-(\overset{\overset{\displaystyle OH}{|}}{CH}-CH_2)_x-\overset{\overset{\displaystyle OH}{|}}{CH}-CH_2-$$

(iv) Sodium polyacrylate,

$$\overset{\overset{\displaystyle COO'Na^{\cdot}}{|}}{CH}{=}CH_2 \longrightarrow -\overset{\overset{\displaystyle COO'Na^{\cdot}}{|}}{CH}-CH_2-(\overset{\overset{\displaystyle COO'Na^{\cdot}}{|}}{CH}-CH_2)_x-\overset{\overset{\displaystyle COO'Na^{\cdot}}{|}}{CH}-CH_2-$$

In all these cases the early stages of polymerisation obviously depend on the formation of covalent molecules, and it would be illogical to set any limit on the length to which the chains of carbon atoms may be extended when the conditions are favourable.

With this background of experimental facts in his mind, the author has looked round for similar structures amongst natural products and claims to have found them in carbohydrates, such as cellulose, and especially in caoutchouc. Thus he supposes that the molecule of caoutchouc, of the composition $(C_5H_8)_{1000}$, contains 13,000 atoms, all united by normal covalencies, and has a molecular weight of 68,000. On the other hand, he has prepared a polystyrol $(C_8H_8)_{6000}$, with about 100,000 atoms in the molecule and a molecular weight of 600,000.

These highly polymerised products form a separate group of organic compounds, since the length of the chain necessarily varies in individual molecules and only a statistical average can be determined, whereas in other synthetic products large molecular weights may be obtained by processes which give rise to identical molecules throughout, as in the more complex dyestuffs or drugs. The average length of the 'thread' can, however, be estimated by a variety of methods. The most important of these depends on finding a formula to express the relationship between the length of the thread and the viscosity of a solution of given concentration.

In the case of roughly spherical molecules the 'specific-viscosity' does not depend to any large extent on the size of the molecules, but for thread-like molecules the specific viscosity increases proportionally with the molecular weight, since the ability of the fibres to impede the movement of the fluid increases with the length of the fibres, and would be correspondingly reduced if the fibres were broken up into shorter lengths. The precise form of the relation between viscosity and length of thread is perhaps open to dispute, but the method has proved invaluable in providing a method of estimating (by extrapolation) the length of threads which are too long to be measured by other methods.

The most trustworthy of these other methods depends on attaching some other radical to the ends of the chain. This radical is then estimated quantitatively (as in recent work on the methylation of cellulose and starch) and the proportion of end-group can be used to deduce the length of the chain. This method can only be used in the case of the smaller threads, but when combined with measurements of viscosity it provides data which can be used for extrapolation to greater lengths.

The existence of aggregates, held together by secondary valencies or van der Waals' forces, is freely admitted in the case of soaps and many other substances of moderate molecular weight, which owe their colloidal properties to the formation of micellar aggregates; but no such aggregation is needed to produce colloidal properties in 'eucolloids' containing from 10^3 to 10^5 atoms of carbon in each molecule. The author therefore believes that the thread-like molecules of cellulose or rubber, although aggregated into bundles in the solid state, may be separated completely into individual threads by dispersion in a suitable medium.

This deduction is fully justified by the contrast between the strength of the carbon to carbon bond, either in the diamond or in an organic compound, and the feebleness of the forces by which molecules are held together in the volatile fusible crystals of a typical organic compound. The only question in dispute is therefore the possibility that under some conditions this separation may still be incomplete.

In this respect Prof. Staudinger has put forward a common-sense view, which will be widely welcomed, especially by chemists who have retained their reverence for structural formulæ and their faith in the quadrivalency of carbon. It is indeed an agreeable sign of the times that organic chemistry in the hands of Staudinger, and inorganic chemistry in the hands of Prof. W. L. Bragg, have provided simultaneously such attractive examples of large molecules, constructed in strict accord with the most orthodox theories of chemical structure; and the reviewer can recall few lectures to which he has listened with greater pleasure than that of Bragg to the Mineralogical Society on the "Structure of the Silicates" and Staudinger's lecture to the Solvay Institute on "Large Molecules", when the floor was littered with glucose molecules, in the form of half-inch lengths of match-stick, which he had broken off from his rods and bundles of cellulose molecules.

The present volume will be read with interest as a full account of the story which was then told in such delightful outline.

T. M. L.

Sulphur Bacteria

Sulphur Bacteria: a Monograph. By Prof. D. Ellis. Pp. ix + 261. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1932.) *21s.* net.

THE sulphur bacteria belong to that remarkable group of autotrophic organisms, the members of which have adopted eccentric modes of metabolism in which unusual sources of energy are tapped. In their case it is the partial oxidation of sulphuretted hydrogen, or perhaps rather of the HS′ ion, with formation of free sulphur. At the same time, carbonic acid is reduced and made available as a source of carbon compounds. Nitrogen can be assimilated from ammonium salts. These materials and some mineral salts are all that is required for the continued growth and well-being of the organisms. The group is confined to organisms which have sulphur globules in their cells. The further oxidation of this sulphur to sulphate, which undoubtedly occurs, has not been proved to be connected with the vital activity of the cells. Sometimes the sulphur is excreted and undergoes oxidation outside the cell.

A feature of great interest in the group is the occurrence of coloured organisms (rhodo-thiobacteria) and much discussion has taken place as to the nature and function of the colouring matter. The prevailing opinion appears to be that by its aid the organisms are enabled to utilise the energy of light in the assimilation of carbon from carbon dioxide. The sulphur metabolism of these coloured organisms seems, however, to be the same as that of the leuco-thiobacteria, so that they have two strings to their metabolic bow.

Considerable practical difficulties arise in the study of the group; especially, perhaps, that pure cultures are difficult to obtain and have not yet in all cases been attained and that the organisms are highly pleomorphic.

The author pays great attention to the classification of this large and important group and adopts an original scheme based primarily on a division into the two groups of colourless and coloured sulphur bacteria. These yield between them eleven families, distinguished by differences in morphology and modes of reproduction and ciliation; these again are divided into 23 genera. A full and well-illustrated description is given of the known organisms, and numerous special points of interest are discussed in separate chapters: such as the intimate structure of the cell, irritability, the mechanism of ciliary motion, etc.

Finally, a very complete account is given of the work on the colouring matter of these organisms. This was first investigated by Ray Lankester in 1873, but the composition and relations of the two colouring matters which are present have not yet been settled.

The sulphur bacteria play an important part in Nature in the sulphur cycle, in which the combined sulphur of the amino-acids of the protein molecule is brought, through the stages of sulphuretted hydrogen and free sulphur, into the condition of a soluble sulphate assimilable by plants, to be reintroduced by them into the protein molecule.

All interested in this fascinating subject will find in Prof. Ellis's book a clear and well documented account of all that is known about it. A. H.

World Civilisations

The History of World Civilisation: from Prehistoric Times to the Middle Ages. By Prof. H. Schneider. Vol. 1. Pp. xiv + 360. Vol. 2. Pp. vi + 361–908. (London: George Routledge and Sons, Ltd., 1931.) *42s. net.*

THIS important and well-known book has been translated from the German, quite competently, though with a good many slips in proof correcting. It naturally suggests the still more famous book of Spengler, which it resembles in the wide sweep of its survey, the facility of its comparisons and the insistence on the rise and fall of civilisations. It is, however, a much weightier book for several reasons. In the first place, it is based on a thorough and scholarly study of the materials; Dr. Schneider's knowledge of the early history of all the civilisations he treats—Egyptian, Babylonian, Greek, Roman, Indian and Chinese—is amazing. In the second place, he is not obsessed by the fallacy which commended Spengler's work as a sensation but undermined its real value, namely, that we are in presence of the decadence of our own civilisation. In the third place, Dr. Schneider is a professor of philosophy and hence by his profession and habitual ways of thinking is always trying to see his subject as a whole.

Now, as human civilisation is one great connected process, this is a prerequisite of the highest importance. At the same time it has led the author

into many doubtful positions—one in particular—which have been noticed with marked disapproval by the specialists and are likely to prejudice the public against the high value of the work as a whole, unless they are pointed out and guarded against at starting.

This one most insistent theory is that of the origin of all civilisations from a northern land and northern peoples, who, accustomed to see the sun disappear entirely in the winter and be born again in the spring, conceived a solar religion which Dr. Schneider traces in the mythology of all. The good and supreme Being is in conflict with a treacherous and malign power which for a time subdues him, and then by various devices he is brought back to life and beneficence again. This so-called 'Cimmerian hypothesis' is not of course generally accepted, but it would be a grave mistake to rule out of consideration any light that it may throw on the dark places of primitive man, and the suggestions which Dr. Schneider is able to make on this basis are often surprisingly enlightening.

The other side, on which the book is most likely to arrest the general reader, is the constant tendency to see analogies in the upward course of the various civilisations described. Egyptians are compared with Babylonians at every turn, and Jews with Greeks and Romans. When we reach the final sections of the book, in which India and China are dealt with much more summarily than the more western peoples, this method is predominant. The assumption always is that each civilisation follows a similar course to that of others, in main outline, with differences due to the various endowment and circumstances of each. Assuming the similarity, the contrasting points stand out more clearly and become more significant of the character of the people to whom they are due. Thus the great gods of India, Indra Agni and Varuna, correspond in a general way to those of the Greek mythology as seen in the "Iliad", but in India they are less clearly visualised and less differentiated. As that power was feebler among the Indians, plastic art achieved nothing like the Zeus of Phidias or the Hermes of Praxiteles.

The section on China is specially interesting from this point of view. Treating the Chinese as most like the Greeks, but crediting them with a mainly independent evolution, Schneider finds that Lao Tzu corresponds more or less to Xenophanes and Confucius to Pythagoras. Both teachers approached very closely to the Greeks though they did not quite attain their level. "Lao Tzu's monism was scientifically on a lower plane than Parmenides and Heraclitus and the criticism of Confucius did not culminate in a Socratic method of bringing valuable knowledge to birth." The reader will notice how the method, which may sometimes strike him as fanciful, has the supreme merit of making the whole story alive and fascinating, and if he wishes to criticise or supplement, so much the better.

The book as a whole is a masterly performance and the sequel will be awaited with great interest. The present two volumes bring us down only to the threshold of the Middle Ages. Chu Hsi, who died in 1200, is the last great man touched on in the Chinese section, and treated somewhat cavalierly. The fact that these volumes stop at that point partly explains what will appear to a careful reader the most serious weakness of the book. Exact science, the ordering of their world by what they had ascertained of the laws of Nature, does not receive sufficient attention. There is too much of their theological beliefs, too little of what they were learning and practising all the time about the world they lived in. Let us hope that this will receive due acknowledgment when science was reborn in greater strength after A.D. 1200.

F. S. MARVIN.

The Insect Menace

The Insect Menace. By L. O. Howard. Pp. xv + 347 + 32 plates. (London: D. Appleton and Co., 1931.) 12*s*. 6*d*. net.

DESPITE the fact that human health and happiness rest on biological foundations, it is surprising how slight has been the incorporation of biological knowledge in current public opinion. For this condition of affairs the biologist himself has not been without blame, in that he has failed to realise that none but the trained specialist can hope to understand the jargon of technical terminology, in which his researches are written. Since the general public provides much of the sinews, which make biological research possible, it seems only fair that its members should be provided from time to time with a readily intelligible account of the progress that the biologist is making in solving problems of human import. In no biological field does the stream of research flow so rapidly as in that of entomology, and in this book the author, who successfully directed the affairs of the United

States Bureau of Entomology for many years, sets himself the task of educating the lay mind in the methods by which the entomologist is coping with the depredations of insect pests.

In the initial chapters Dr. Howard explains why insects with their vast range of structural adaptations, extending over a period of forty million years, have achieved such a marked degree of ascendancy over practically all other living organisms save man. It is further shown that the achievement of economic status as pests by insects has been mainly determined by human agency, which has also fostered their spread from region to region and country to country by reason of the facilities offered by modern systems of rapid transport.

If one has any doubts of the extent of the damage caused by insects, the formidable figures —even approximate as they are—furnished by statisticians will go far to remove them. For example, during the year 1919 it was estimated that insect ravages were responsible for a reduction of four hundred million pounds in the value of the crops of the United States alone. It almost staggers the imagination to think of the extent of the losses reckoned in terms of the crops of the whole world. It is readily comprehensible how these losses must and do affect the prices of many staple commodities such as cotton, sugar, maize and wheat as well as the conditions of the labour market in different parts of the world. Then again there is still to be considered that toll of human health and efficiency, to say nothing of domesticated animals, which is exacted by the pathogenic micro-organisms, that are transmitted by insects, blood-sucking and non-blood-sucking, in both tropical and temperate countries.

In view of all the facts, there is cause for congratulation that to-day there are more than seventy countries which have come to realise the importance of applied entomology, and are now providing staffs of trained entomologists, who either act in an advisory capacity or carry on research on specific problems. It is recognised that human resource and ingenuity are being taxed to the utmost to cope with the insect menace. Methods of attack vary with the individual insect species. Now it may be biological, as in the case of the cottony-cushion scale of California and the Levuana caterpillar of Fiji. Again it may be mechanical and chemical, as in the case of the cotton-boll weevil; or again it may be legislative, involving stringent measures of quarantine and eradication, as in the case of the Mediterranean fruit-fly. That solutions of what at one time seemed hopeless problems have been achieved is shown by the present negligible status in the United States of the Rocky Mountain locust, the cotton-boll weevil and the Mediterranean fruit-fly. Elimination of the breeding grounds in the North-West by settlement and cultivation has obliterated the swarms of the first of these; in regard to the second it has been shown that cotton can be successfully grown despite the weevil, if the plants are dusted with arsenate of lime; and the dreaded fruit-fly introduced into Florida in 1929 was speedily eradicated by the destruction of all infested fruit and restriction of shipments of fruit from infested to non-infested areas.

In conclusion, we would say that Dr. Howard has admirably achieved the purpose with which he set out. The educated layman will find no difficulty in following his arguments, and we can guarantee that the reader's interest will be sustained from cover to cover. The book should enjoy a wide circulation among those who are anxious to extend their knowledge of Nature's ways.

A. E. CAMERON.

Short Reviews

A Scheme of Egyptian Chronology: with Notes thereon including Notes on Cretan and other Chronologies. By Duncan Macnaughton. Pp. xii + 406 + 19 plates. (London: Luzac and Co., 1932.) 25*s*.

THE author here follows up certain suggestions in reference to Egyptian chronology which were put forward in his "Scheme of Babylonian Chronology", but were not worked out. Further study has now shown him the possibilities of a number of clues to the dating of the early Egyptian dynasties. His theory, broadly, is that the 'births' of the gods in the Palermo Stone refer to the commencement of planetary cycles, which could probably only occur in historic times at a certain period, reinforced by his interpretation of the evidence of the list of Eratosthenes, and other calendrical and astronomical evidence.

The author himself regards his results as of varying value, some being classed as highly probable and others as only "mere possibilities". The result as regards the crucial dates are certainly high in comparison with more conservative systems. Thus Dynasty I is put at 5776 B.C. as against the 4360 B.C. of Petrie or the 3315 of Meyer. The author is scrupulously fair in the full statement of his data, and even those who do not agree with him, will find his book a useful compendium of the facts relating to the controversial questions of Egyptian chronology.

The Scenery of England: a Study of Harmonious Grouping in Town and Country. By Dr. Vaughan Cornish. Pp. 125 + 8 plates. (London: The Council for the Preservation of Rural England, 1932.) 3s. 6d. net.

DR. CORNISH here presents to us the beauty of England in a succession of charming word-pictures from his rich store of personal impressions of the many types of landscape which the country affords, including the Lakes, the Peak, the Fens, the Cotswolds, Dartmoor, the New Forest, the Dorset coast, Wiltshire downs and many other parts. This, in a book of so modest a compass, should be a more effective method of rousing public interest in the work of the Council for the Preservation of Rural England than a more categorical description of the country, county by county, or district by district. Dr. Cornish throughout lays stress on the importance of making buildings harmonise with the landscape, and he concludes with appendixes on the aims and objects of the Council and powers and duties of affiliated local authorities.

The Council's attitude towards modern developments is thoroughly sane and well-balanced, emphasising the complementary relationship between town and country and the necessity for planning England as a whole, never suggesting that it would be either possible or desirable to hamper the healthy growth of cities. The face of England as regards extent of area is still predominantly rural by a wide margin, and it would no doubt be to the advantage of the nation that it should remain so. Hence it seems to us that the efforts and deliberations of the Council should always be made with an eye to the possibility that the population will continue to increase indefinitely.

If the present huge population of England were ever to double itself and remain concentrated in a few unwieldy 'conurbations', it is difficult to see what could be done to prevent a large fraction of the area of the country from wearing a heavy suburban cloak, even though the remaining rural districts might still be solitary and the remoter mountain regions practically uninhabited wilderness as at present. L. C. W. B.

The Call of the Bush: Wanderings of a Nature Man on the Murray River. By Harold Priest. Pp. 240 + 16 plates. (London: T. Werner Laurie, Ltd., 1932.) 12s. 6d. net.

THIS is the record of a long tramp along the course of the Murray River, the author shifting for himself and 'living on the country' as he went, though he ultimately joined up with a couple of cattlemen and accompanied them for a time. His observations on the great river and the various human and animal types which frequent it are varied and they are interestingly told, but the book would have been even better than it is had there been more detailed natural history and less reflective 'padding'. One interesting observation is on the coloration of the ticks infesting the common Australian monitor (miscalled 'guana' or 'goanna'), which are black when adhering to the black areas of the reptile's skin, and yellow when on the pale ground, and this, as the author says, suggests that this adaptive hue, which renders them very difficult to see, means that they have had to protect themselves against removal by other agencies as well as their hosts. Another interesting fact recorded is that domestic cats kept in the wilds bring their kittens fishes as well as other animals, indicating that the animals' well-known fondness for these has its foundation in a natural preying habit.

Pila (the Apple-Snail). By Dr. Baini Prashad. (The Indian Zoological Memoirs on Indian Animal Types, edited by Dr. K. N. Bahl, No. 4.) Pp. xi + 83. (Lucknow: Methodist Publishing House, 1932.) 2 rupees.

THIS laboratory manual on the snail now studied in most eastern universities as a type of gastropod mollusc is itself a model of what such a book ought to be. It is well illustrated, and contains not only a description of the anatomy of the subject and practical directions for its dissection, but also a synopsis of the eight Indian species of the genus *Pila*, and some interesting bionomical notes. From these it is plain that the apple-snail is the most versatile of the gastropods—or indeed, of all Mollusca. Usually a denizen of fresh-water, it can, in the case at least of *P. globosa*, tolerate that which is brackish; usually vegetarian, it may eat dead animal matter. It has both aquatic and aerial respiration at its command; it can swim as well as crawl in water, and yet can travel overland and even climb trees, while it lays its eggs on land, and specimens left dry in a cupboard rivalled the celebrated desert-snail of the British Museum by being found alive after five years.

The Animals came to Drink. By Cherry Kearton. Pp. 189 + 31 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1932.) 6s. net.

IN the introductory note the author states that he would "be thankful if this book could act as a counterblast to the many animal stories, so constantly appearing, which are based on utterly false or distorted natural history", and his desire will certainly be fulfilled if this volume achieves the popularity it deserves. The reader's attention is held from start to finish and the genuine ring of truth is established as, in the form of a story, the writer recalls his own long experience of African wild life. The narrative centres round the wanderings of an *impalla*; the insistent demand for water results in the description of many incidents which show the author's patience and keenness of observation. The volume is well illustrated.

Water Pollution Research

By DR. A. PARKER

THE growth of industry and of the population during the last century, especially in the north of England, gave rise to several undesirable conditions, including gross contamination of rivers, which in some cases became little better than open sewers. A plentiful supply of water of good quality for domestic and agricultural purposes is one of the major factors in public health, and large quantities of comparatively pure water are required for many industrial processes. Available sources, both surface and underground, of unpolluted water are gradually being depleted and there is no doubt that many rivers which are at present polluted will have to be utilised in the future as sources of supply, after treatment, for both domestic and industrial purposes. Further, the problems of river pollution are of importance in that they affect not only the health and recreations of the population but also the interests of farmers, landowners and fishermen. It is not surprising, therefore, that attention has frequently been directed to the need for satisfactory methods of preventing or reducing pollution.

It was recognised by the Royal Commission on Sewage Disposal, whose comprehensive inquiry during the years 1898–1915 produced results of great value, that satisfactory methods of disposal of polluting liquids from industrial operations were in many cases either unknown or impracticable, and that the problems involved could not be solved without further knowledge. One of the recommendations of the Commission was the establishment of a central authority the duties of which should include the investigation of problems in the purification of polluting discharges and the collection and correlation of the results of investigations by others. Since 1915, the importance of the subject has been stressed on several occasions. In February 1927, public opinion was focused on the matter by a deputation, representative of the British Waterworks Association, the Salmon and Trout Association and other authorities, which was received by the late Lord Balfour, then Lord President of the Council. In consequence of the views expressed by these and other independent authorities and by several Government departments, the Water Pollution Research Board was set up in June 1927 by the Department of Scientific and Industrial Research. This Board was appointed to submit schemes for research on the prevention of the pollution of rivers and other sources of water supply and on any relevant matters affecting the purity of water supplies, and to supervise approved investigations.

Since its appointment, the Board has initiated investigations of the problem of disposal of effluents from beet sugar factories, the base-exchange process of water softening, the causes of the corrosive and plumbo-solvent action of certain waters on mains and service pipes, and of bacteriological and physico-chemical problems associated with processes of purification of sewage. In addition, a comprehensive scientific survey of the River Tees was begun early in 1929. The research staff has also assisted other investigators by directing attention to appropriate scientific and technical literature and by indicating the most promising methods of attacking the problems to be solved. In this connexion, informative summaries of current literature relating to water supplies, sewage, trade waste waters, river pollution and kindred subjects are systematically prepared and published monthly.

Of the investigations already mentioned, that dealing with effluents from beet sugar factories and the survey of the River Tees have reached the most advanced stages. It is proposed, therefore, briefly to describe these two investigations and the more important results obtained. Incidentally, as an illustration of the greater interest now being taken in the problems of water supply and river pollution, it should be mentioned that a session of Section B (Chemistry) at the recent meeting at York of the British Association was devoted to a discussion of the survey of the River Tees. In addition, Sections D (Zoology) and K (Botany) held a joint discussion on biological balance in fresh water, while the organisation required for recording water level and river flow in the British Isles was discussed in Section A (Mathematical Science and Physics).

When the Water Pollution Research Board began its activities, the beet sugar industry had only recently developed on an extensive scale in Great Britain, but already several serious cases of the pollution of rivers by the waste waters had occurred. Preliminary work soon indicated that it might be advisable to suggest modifications in the factory processes so as to reduce the quantities or alter the composition of the effluents rather than to consider only methods of purification. It was important, therefore, that the investigation should be proceeded with as rapidly as possible, before other factories were erected.

On arrival at the factory, the beets are conveyed by water carriage along flumes to washers in which they are washed to remove adhering soil and debris. In a factory of average size, 1,000–1,500 tons of beet are dealt with each day and the total quantity of fluming and washing water varies from 2·5 to 3·5 million gallons. After washing, the beets are cut into small slices or cossettes from which the sugar is extracted with hot juice or water, usually in a battery of diffusers; the diffusers are cleaned periodically by washing with water. The spent cossettes are then pressed to reduce their moisture content. Water

removed from the spent cossettes, together with the washings from the diffusers, is generally known as process water and amounts to 300,000–500,000 gallons per day. Purification of the solution of sugar is effected by several processes and the purified juice is evaporated to crystallise the sugar. A large quantity of cooling water is required during the concentration of the juice, and from 75 to 80 per cent of the water in the juice is removed and condensed in the process. The total quantity of water from the condensers is of the order of 3 million gallons per 1,000 tons of beet treated; this water is often used again in the flumes for carrying the beets to the washers. From this brief description of the factory processes, it will be noted that the principal effluents for disposal are fluming and washing water, 2·5–3·5 million gallons per 1,000 tons of beet, and process water, 300,000–500,000 gallons per 1,000 tons of beet. The fluming and washing water carries soil and beet debris and contains small amounts of dissolved organic and inorganic substances. It is definitely polluting in character, but though larger in quantity it is not so objectionable as process water. This latter effluent contains 0·2–0·4 per cent of sugar, ferments rapidly on storage and takes up large quantities of oxygen from any river into which it may be discharged.

As a result of the investigation during 1927–30, the Water Pollution Research Board definitely concluded that by suitable modifications in the factory processes, the whole, or at least the major quantities, of the fluming and washing water and of the process water could be re-used, leaving little or no effluent for disposal. Certain factories have for several seasons re-used the fluming and washing water after simple treatment by screening and sedimentation to remove solid matter, and the re-use of this water has proved to be entirely satisfactory. At some factories the cossettes are extracted by a continuous process of diffusion in which the water removed from the spent cossettes is returned to the diffuser. In this process there is very little waste water for disposal. Even with the intermittent process in a battery of diffusers, large scale trials in the factory have shown that after preliminary treatment with lime or by other simple methods, the process water can in large measure be re-used in place of fresh water. If the fluming and washing water is re-used, then the effluent from the condensers requires consideration. This effluent is not very polluting in character, but it is advisable that it be cooled before discharge to a river, or it may be cooled and re-used.

Although it had been shown that the waste waters from a beet sugar factory could be largely re-used, it was realised that it might be necessary on occasion to discharge a proportion of the waste waters or that some factories might prefer to purify the wastes sufficiently to allow of their discharge into a river rather than to re-use them. After preliminary experiments in the laboratory, it was decided that, as a method of purification, the process of biological oxidation on percolating filters showed promise of success. This process, which is similar to that in operation at many sewage works, was tried therefore in laboratory and large-scale experiments. In addition to the chemical examination of the effluents before and after treatment, the fauna and flora of the filters have been systematically studied, and it has been shown that, under certain conditions, beet sugar factory effluents can be sufficiently purified by biological filtration to allow of their discharge, except into the smallest streams, without causing serious pollution. It has been demonstrated, therefore, that gross contamination of rivers by effluents from beet sugar factories can be avoided and there is no doubt that during the past two or three years this type of pollution has been much reduced.

The survey of the River Tees was undertaken with the object of obtaining more precise information than was hitherto available on the effects of different kinds of effluents, both sewage and industrial, on a river, and with the object of assessing the power of a river to recover from the effects of polluting discharges. This survey provides a good example of what can be achieved from carefully planned co-operation between specialists in different branches of science, for it has included hydrographical, chemical, bacteriological, botanical and zoological observations and experiments. In addition, records of rainfall have been collected for correlation with measurements of river flow.

From the hydrographical measurements, it has been shown that the water in the estuary at depths below one fathom has a tendency to move up river over each tidal cycle of ebb and flood. The water in the top layer, however, has a strong net movement down river, and the volume moving down river in this layer is greater than the net volume moving up river in the lower layers. A circulatory system is thus set up and is superimposed on the to-and-fro movement of the tides. It has been concluded, therefore, that polluting matter is not readily conveyed to the sea unless it is in the surface layer when it reaches the estuary.

Large quantities of crude sewage and of industrial effluents are discharged into the estuary of the Tees, especially in the section from Stockton to Cargo Fleet. The principal industrial effluents are those derived from coke ovens which contain tar acids, naphthalene, cyanide, etc., and spent pickle liquor, which is an acid solution of iron produced during the cleansing of iron and steel. Oxidation of the sewage and effluents occurs in the estuary at the expense of dissolved oxygen. The Tees was formerly a noted salmon river, but for many years large numbers of fish have been killed in the estuary, especially salmon and sea trout smolts during their migration in the spring to the sea. Various observations and experiments

included in the survey have proved that in 1930 and 1931 the death of migrating smolts was not due to the deficiency of dissolved oxygen but to cyanides, which were frequently found in lethal concentrations. Other poisonous substances, including tar acids, were not found in toxic concentrations and it has been concluded that in the absence of cyanides, migrating smolts would not have been killed in 1930 and 1931. This conclusion marks a distinct step forward, for although several explanations had previously been offered, it had never before been suggested that cyanides were responsible for the death of fish in the River Tees. Another interesting result of the survey is that experiments in the laboratory and on a semi-technical scale have demonstrated that cyanides in coke oven effluents can readily be converted into relatively non-toxic ferrocyanide by treatment of the effluents with spent pickle liquor and lime.

In the non-tidal reach of the Tees, there is only one point at which any large quantity of polluting matter enters and this pollution is derived from sewage. Further downstream, for a distance of about 15 miles, there is no polluting discharge of any importance. A study has been made, therefore, of the effects of sewage pollution on the biology of the river and of the factors which influence the rate of self-purification of a river from pollution by sewage. It appears that temperature is the most important factor, so that the rate of self-purification is much greater in summer than in winter. In determining the relative rates of self-purification under various conditions, it has been necessary to calculate the total quantities of different constituents of the river water from the results of chemical analysis and measurements of volumes of water and river flows. The occurrence of certain plants and animals has been correlated with the conditions of the water as determined by chemical analysis and several new and little-known algæ have been discovered. In addition, useful additions to knowledge have been made with regard to the food of fish.

Cod in Danish Waters

COD are present in all Danish North Sea waters and extend northward through the brackish Baltic Sea into the still more brackish Gulf of Bothnia almost (but not quite) to its northern extremity. Elaborate researches upon the cod in all these waters have been carried out by a Danish investigator, Dr. E. M. Poulsen, the results of which have been published recently in a comprehensive report.*

In Section I of the report data regarding the bathymetric distribution of the fish in Danish waters are given. In the North Sea, cod are most abundant in depths of less than 100 metres. Between 100 and 200 metres they are relatively scarce, while at depths of more than 200 metres they are seldom caught. What few cod there are present in these deeper layers are almost entirely old and large fish. In the Baltic, around Bornholm, cod are most numerous from 40 down to 100 metres, at which depths the water is less brackish than in the overlying layers. In the Kattegat, on the other hand, the fish favour depths of from 40 to 60 metres.

Observations on the spawning periods of the cod in these different regions produced very interesting results. In the Kattegat, spawning begins in February, reaches a maximum in March, and finishes about the end of April. In the Belt Sea spawning may extend into the first half of May, while still farther north, in the Bornholm Deep, spawning continues from April until August with June as the main spawning month. Contemporaneous hydrographical data reveal that the cod spawn in water the temperature of which lies between 3° C. and 7° C. The displacement of the spawning season from early spring far into the summer, on proceeding from the Kattegat into the Baltic, corresponds with the different times at which the bottom waters reach this temperature.

Cod larvæ occur throughout the whole of the area investigated, but are most numerous in the North Sea, the South West Kattegat, the Sound, Belts, and Western Baltic, and are relatively very much scarcer in the Skagerak, the North East Kattegat, and in the Baltic proper. The larvæ are peculiarly abundant in front of certain marine ridges which intercept the in-going North Sea currents in the Little Belt, at the Gedser Reef, and at Dragden in the Sound. Hydrographical investigations show that the ingoing salt-water currents are largely blocked at these ridges. Larvæ from the North Sea brought in by the currents are therefore largely intercepted by them and accumulate in great numbers on their seaward sides.

During the period 1917–1927 good and bad survival years for the fry are stated to have alternated regularly, the years 1917, 1919, 1921, 1923, 1925, and 1927 having been good survival years, while the intervening years were bad. The years 1928 and 1929 are described somewhat vaguely as being neither good nor bad but "to some extent normal".

The most interesting and important part of the report is that in which the author records his attempts to determine the causes underlying these annual fluctuations in the abundance of cod fry in these waters. At the outset a certain amount of evidence is put forward which suggests that fluctuations in the number of eggs produced from year to year are not to any appreciable extent correlated with fluctuations in the number of larvæ later produced.

* Erik M. Poulsen. "Biological Investigations upon the Cod in Danish Waters". Meddelelser fra Kommissionen for Danmarks Fiskeri-og Havundersøgelser. Serie: Fiskeri. Bind IX., Nr. 1., pp. 1-148. C. A. Reitzels Forlag, København, 1931.

A distinct correlation is found to exist, however, between the temperature of the bottom waters in March–April–May and the quantity of larvæ which can be caught by standard methods in these months, a relatively high temperature being coincident with a good larval yield and vice versa. The reason for this correlation is claimed to be that temperature conditions are directly responsible for the abundance or otherwise of the planktonic food organisms upon which the fry depend for their survival. The radius of action of a tiny cod larva is very small. If it does not find abundant and easily available food as soon as its yolk is used up it dies.

Dr. Poulsen has also found an apparently significant relation between the temperature of the surface water in January and February and the number of larvæ obtainable in the spring months following. The reason for this, he believes, undoubtedly is that when the surface water in mild winters is comparatively warm the winter minimum of planktonic organisms does not sink so far as in more severe winters. (In this connexion it is interesting to recall that in 1927 Johansen found that the number of plaice fry in the Belt Sea was correlated with the number of days in which the water was covered with ice, and the temperature of the surface water in January and February.)

A definite relation is also established between the salinity of the bottom waters in November and December and the number of fry present in the following spring both in the Belt Sea and to a lesser extent in the Kattegat. This correlation, it is pointed out, cannot be due to any direct influence. Spawning does not begin until January at the earliest and larvæ do not appear until about the end of February. The following tentative explanation is therefore put forward. In the autumn an annual migration of large and sexually mature cod is known to take place from outside into the Belt Sea. This migration is dependent upon an autumn inflow of salt water from the North Sea. The larger the inflow, the greater the number of cod which come in with it. Particularly large numbers of eggs are then spawned and a large brood of larvæ results. At the same time, a large inflow of North Sea water produces a condition of high salinity in the Belt Sea and in the Kattegat.

This explanation implies that fluctuations in the numbers of eggs laid produce corresponding fluctuations in the resulting larval broods. This hypothesis may hold good in the Belt Sea but the author himself, in another part of his report, points out that it does not appear to be true as a general rule. It is to be hoped, therefore, that Dr. Poulsen will continue these researches and that this report will in due course be followed by another containing new and illuminating information on these interesting and important points in the life history of the cod in Danish waters.

G. A. S.

Low Altitude Auroræ

AN unusually low aurora was witnessed on March 8 of this year at the Auroral Observatory, Tromsø, Norway. The height was determined photographically by the Director, L. Harang, working with Dr. W. Bauer (of the Photophysical Laboratory, the Danzig Technical High School), who have made a brief joint report of their work in *Gerlands Beiträge zur Geophysik* (Bd. 37, pp. 109–115, 1932). At the suggestion of E. Brüche, Berlin, two film cameras were in use at the two base stations (43 km. apart) from which simultaneous parallactic photographs were made; this was in order that, by taking short exposures of a few seconds, a continuous record of the development and changes of auroræ might be obtained. On the two evenings of March 8 and 9, 1932, about 500 pairs of photographs of bows, bands, draperies and rays were taken, during intense displays of the northern lights. A series of 20 pairs of these pictures, covering a period of only 75 seconds, on the night of March 8, disclosed a particularly interesting phenomenon.

At 20.45 G.M.T. an intense yellow-green auroral bow with a deep-red lower edge appeared in the north, at an elevation above the horizon of about 13°; it was found to be 290 km. distant, at an altitude of 77 km. Within 40 seconds it drew southwards by 20 km., and penetrated the atmosphere further, to 75 km., while its eastern portion dissolved, so that the bow ceased to be in the field of the camera. Suddenly, during a few seconds, another bow developed, 20 km. behind the first, that is, at the distance where the latter originally appeared; the second bow, however, was lower, its measured height being only 65 km. After 15 seconds its height quickly increased to 80 km., and it receded to 350 km. distance, while the red colour vanished from the lower edge. This bow also then drew slowly southwards, while its right end rose to 100 km.; this disclosed a third faint bow, lying at 90 km. height and 70 km. behind the second one, the gradual southward motion of which it followed. The time during which the second bow was below 75 km. was less than 20 seconds.

The outstanding character of this observation is well illustrated by the diagram here reproduced (Fig. 1), from the paper referred to. In column *A* are shown all the measured heights of the yellow-green auroral bows observed at Tromsø during the period February to October 1929. In the middle column *B* are shown the heights of the red-edged yellow-green bows observed there on March 8, and in column *C* the heights of other yellow-green bows observed on the same evening. The diagram shows that the heights usually exceed 90 km., but, rather rarely, come down nearly to 80 km., as Prof. C. Størmer found. The quite exceptional nature of the lower red-edged

bow of March 8, extending down to 65 km. (or possibly even less) is evident.

We are still ignorant of the precise mode in which the auroral light is produced, but it seems likely to be due to the entry into the atmosphere of charged particles from outside; the sign of the charge, and the speed of the particles, are unknown. Their penetrating power can be conveniently stated (as for α- and β-particles in the laboratory) in terms of the equivalent thickness of air at normal density which they traverse. This cannot be accurately inferred from the measured heights of the lowermost edges of auroræ, because of uncertainties as to the composition and temperature of the air at great heights; but there can be little doubt that particles which come down to 65 km. traverse at least five times as much air as those that come down to 80 km. Thus the newly observed aurora suggests that, at times, particles enter the atmosphere with a penetrating power five times as great as that of those (themselves unusually penetrating) that come down to 80 km. If this interpretation be correct, the extension in the range of our knowledge of these particles is no small one.

Another reflection is prompted by the extremely fleeting nature of this low aurora. Throughout their many years of auroral photography, Størmer, Vegard and Krogness have never measured so low an aurora; of course a great many auroræ the heights of which have not been determined have appeared during this period, and much of their work has been done at stations south of Tromsø. Apart from the red edge, which is not unique, the low bows now measured were not specially outstanding, and there was no obvious indication of their unusually low altitude. May not many such low bows, perhaps equally fleeting, have passed without recognition of their exceptional character? And may there not occasionally be still lower ones to be discovered by some fortunate or patient observer? The answer seems likely to be 'yes'.

Further, every reduction in the auroral heights substantiated by parallactic measurements increases the credibility of the reports of auroræ extending down to the ground. The gap between a height of 65 km. and the ground is a very large one, it is true, but already we have seen the lowermost measured height reduced from 100 km. or 95 km., as in Størmer's early work, to 80 km. in his later work, and, by McLennan's Canadian observations, to 75 km.; and now, by Harang and Bauer, this is brought down to 65 km.—a total reduction of 30 km. The capacity of auroræ to produce low height records—like that of the weather to surpass its own records of long standing—may be much greater than has been supposed.

In this connexion it may be appropriate, finally, to mention that a new collection of reports bearing on the audibility of auroræ, and on low altitude (ground level) auroræ, has been made by Dr. C. S. Beals, of the Dominion Astrophysical Observatory, Victoria, B.C. The reports come from the northern Canadian auroral belt, and are closely similar in tenor to those collected by Mr. J. Halvor Johnson, which I described in an article in NATURE of March 7, 1931. Dr. C. A. Chant, editor of the *Journal of the Royal Astronomical Society of Canada*, had also collected such evidence, during the years 1907–29. Dr. Beals, after discussing the evidence in his paper (which is to appear in January in the *Quarterly Journal of the Royal Meteorological Society*), regards it as reasonably establishing the occurrence, on very rare occasions, both of auroral sounds and of ground-level auroræ.

S. CHAPMAN.

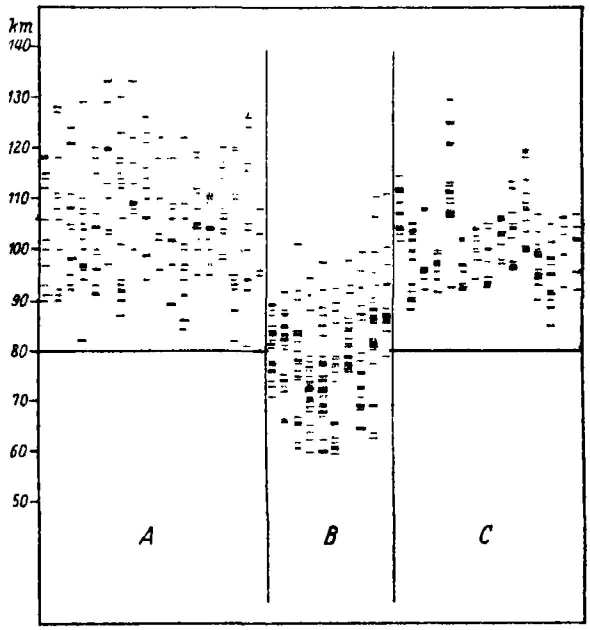

FIG. 1. Heights of auroral bows: *A*, February-October, 1929; *B* and *C*, March 8, 1932. From *Gerlands Beiträge zur Geophysik*, Bd. 37, Heft 1, 1932.

Obituary

PROF. T. GRAY

IT was with profound regret that the many friends of Prof. Thomas Gray learned of his death at Elie, Fife, on September 26. With his passing the Royal Technical College, Glasgow, has lost one of its most distinguished members.

Born at Mid-Calder in 1869, Prof. Gray received his early education at George Watson's College, Edinburgh, and entered the Andersonian College at Glasgow as a student of Prof. Dittmar in 1885. At nineteen years of age, he proceeded to the University of Jena, returning a year later to become assistant to Prof. Dittmar and afterwards to Prof. Henderson. Graduating B.Sc. in the University of London in 1890, his career as a lecturer commenced three years later at the Royal Tech-

nical College and in the same year he was appointed lecturer in chemistry at Queen Margaret College.

The summers of 1899 and 1900 were spent at Jena, where he obtained the degree of Ph.D., and in 1901 he graduated D.Sc., of the University of Glasgow. He also prosecuted his studies at Heidelberg and at the Zurich Polytechnic under Prof. Lunge.

In 1903, on the retirement of Prof. Mills, Dr. Gray succeeded to the 'Young' chair of technical chemistry at the Royal Technical College, and in 1919 was appointed director of the School of Chemistry. He instituted, in the College, the first classes giving public instruction in fuels; and to acquire first-hand knowledge of methods of manufacture and of plant construction, he spent many of his summer vacations in chemical works. During the War period he placed his extensive scientific knowledge at the service of various Government departments, and two outstanding tasks which he undertook were the supervision of the production of benzene and toluene from the Scottish gas works for munition purposes, and an extensive survey of the coals of Scotland with special reference to their suitability for use in blast furnaces and for metallurgical coke manufacture.

The importance of his services during the War and his eminence as a chemist were recognised at the University of Glasgow by the conferment of the honorary degree of LL.D.

In 1918, the Department of Scientific and Industrial Research invited Prof. Gray to supervise the design and organisation of the fuel research laboratories at East Greenwich, and from 1920 he acted as consultant to the Fuel Research Board for three years. At the time of his death he was a member of that Board.

Prof. Gray was a fellow of the Institute of Chemistry and of the Chemical Society, and acted as secretary for ten years and chairman for two years, of the Glasgow Section of the Society of Chemical Industry. Among the committees on which he served, were the Education Committee of the Institution of Gas Engineers, the Scottish Coal Survey Committee, and the Committee on Sampling and Analysis of Coal of the Fuel Research Board, of which he was chairman. His services as an examiner in chemistry were retained by the boards of various institutions, among which were the Faculty of Physicians and Surgeons of Glasgow and the Royal College of Physicians and Surgeons of Edinburgh. He was retained by the British Electric Lamp Manufacturers' Association as a consultant, and his services were much in demand as an expert witness in law cases dealing with chemical patents. Many of his scientific papers were published by the Chemical Society and the Society of Chemical Industry and in the *Berichte*.

In analytical work, Prof. Gray carried accuracy to extremes; and in research his cleverness as a glass blower, and his ingenuity in designing apparatus from the simplest material, were remarkable. An ideal teacher, he was held in high esteem by student and colleague alike. He had a quiet and attractive personality, and to have been included in his circle of friends was to have experienced an ever-increasing admiration for a very fine gentleman. W. J. SKILLING.

M. SALOMON REINACH

BY the death of Salomon Reinach, which took place at Boulogne-sur-Seine on November 4, France has lost one of her most distinguished and widely-known sons, who for more than a generation held a foremost place in the world of scholarship and archæology.

Salomon Reinach was born at St.-Germain on August 29, 1858, and, with his two brothers, also destined to attain high distinction in the world of learning, was educated at the Lycée Condorcet. He afterwards attended the École Normale and took the degrees of doctor of law and doctor of letters at the University of Paris. From that time onward his life was devoted to archæological studies, but in no narrow sense. In his view of the past he saw life whole. The breadth of his knowledge of antiquity was equalled by his understanding of it; and it should be no matter for surprise that he attained a universal reputation as an authority in classical scholarship and the history of philosophy, religion and art as well as in archæology.

In 1879 Reinach at the age of twenty-one years became a member of the French School of Archæology in Athens and later acted as the secretary of the Archæological Commission in Tunis. In 1885 he was appointed to the staff of the National Museums and in the same year published his "Traite d'Epigraphie Grecque", a Latin grammar and a handbook of field archæology. These had already been preceded by a manual of classical philology, issued between 1882 and 1884. By the time he was appointed curator of the Museum of St.-Germain and professor at the Louvre School in 1902, his monumental catalogue of the prehistoric collections of that Museum, which has recently been revised and re-issued, had won for him an established position as an authority in prehistoric archæology. Archæological studies took him to Greece, North Africa, southern Russia, Asia Minor, the whole fringe of the Mediterranean and the Danube. In western Europe his expert knowledge extended from palæolithic man to Gauls and Romans; and his acquaintance with the European museums and their contents was probably unique.

Reinach's literary output in the fields of classical scholarship, philosophy, comparative religion, art and archæology was very large. In 1902 he became the director of the *Révue Archéologique*. Throughout his life a stream of papers, monographs, books and articles came from his pen. It was characteristic of his humanistic attitude that he should also contribute to contemporary history and controversy—in this field he wrote *inter alia* a history

of the War and one of the Russian revolution, while the concluding chapters of the latest edition of his "Orpheus" is a masterly review of post-War tendencies in religious and political thought from his special point of view, that of the philosopher and historian who sees current events broadly, not as an ephemeral manifestation of human activity, but as part of a panoramic whole in which the springs of action are deep-rooted in the principles which govern the growth of humanity and the development of civilisation. He admitted himself something of a disciple of Voltaire, and his "Orpheus", a study of the history of religion in which religions are treated as natural phenomena, aroused some antagonism by his attitude towards Christianity. His writing, in truth, was not always uncoloured by emotion, and it was this, perhaps, which sometimes rendered his judgment open to question, as in his endorsement of the authenticity of the 'antiquities' from Glozel. Yet it is a remarkable tribute to the authority and enduring quality of his work that several of his books ran through more than one edition and of the "Orpheus" there were no less than thirty-eight French editions, the translation of the last appearing in England in 1931.

DR. C. B. MARSON

DR. C. B. MARSON, recently appointed head of the Chemical Department of the Hull Municipal Technical College, died suddenly on October 26.

Dr. Marson was apprenticed to Capt. J. A. Foster, public analyst of Hull, and during most of the War was attached to the French army at Verdun. After that he was on the chemical staff of the British Thomson-Houston Company, Rugby. He resigned that post in order to enter on a course in the Department of Coal Gas and Fuel Industries at the University of Leeds, which was terminated by his taking the B.Sc. degree with first-class honours in fuel and metallurgy, and later the Ph.D. degree. Since that time he has been in succession Gas Research Fellow at the University of Leeds, chemist on the staff of the Joint Research Committee of the Institution of Gas Engineers and the University of Leeds, and chief chemist of the Northern Coke Research Committee, stationed at Armstrong College, Newcastle-on-Tyne, until he took up his post at Hull a few weeks ago.

Dr. Marson was conspicuously successful in every post that he filled, and his untimely death has undoubtedly cut short a promising career.

H. J. H.

WE regret to announce the following deaths:

Dr. Marcus Benjamin, industrial chemist and editor of the publications of the United States National Museum, on October 22, aged seventy-five years.

Sir Dugald Clerk, K.B.E., F.R.S., who was elected president of the Institution of Civil Engineers for this year, but was unable to take office owing to ill-health, and was distinguished by his pioneer work on internal combustion engines, on November 12, aged seventy-eight years.

News and Views

H.R.H. the Duke of York, F.R.S.

HIS ROYAL HIGHNESS THE DUKE OF YORK attended the ordinary meeting of the Royal Society on November 10, signed the roll, and was formally admitted a fellow by the president, Sir Frederick Gowland Hopkins. The Duke had been elected on June 16 last. As is generally known, the opening page in the charter book, denoting the Society's inauguration, bears the signatures "Charles-Founder", "James [Duke of York, afterwards James II.] Fellow", and "Rupert"; the latter was the cousin of the reigning monarch. But another signature—"George", is there, and posterity may well conjecture how his name comes to be subscribed in alignment with that of "Rupert", and not beneath it. There was never a George Rupert; the name was that of George of Denmark, who married the Princess Anne. Elected (or brought into) the Society on its anniversary day, in 1704, and not long after Newton became president, it was the latter who waited on the Prince that day (with others), to obtain his signature, and adherence. Queen Anne herself never signed the charter book.

The Royal Family and the Royal Society

THE election of royal personages, subsequent to the year 1820, whether as patrons (being reigning sovereigns), or, as of blood relationship, is of interest. William IV (elected 1831) signed as patron. Queen Victoria inscribed her name on June 20, 1838, the Prince Consort signing below after election in 1840. King Edward VII signed when Prince of Wales, and again as patron (1901). In the former instance he had been elected in 1863, being proposed by Maj.-Gen. Sabine, the president. It would seem that it was not until March 2, 1882, whilst William Spottiswoode was president, that the Prince attended and inscribed his name. Also, in that year, his brother, the Duke of Edinburgh, was elected. Another brother, the Duke of Connaught, was elected on November 8, 1906, on the proposal of Lord Rayleigh, president, attending for admission in December following. His Royal Highness is, happily, still on the roll. His Majesty King George V was elected a fellow on June 8, 1893, when Duke of York, on the proposal of Lord Kelvin and Sir Michael Foster; on becoming Prince of Wales he then inscribed, and again in 1910 as monarch and patron. More recent times have witnessed the election and admission of Prince Arthur of Connaught (1914), His Royal Highness the Prince of Wales (1919, on the proposal of Sir J. J. Thomson, president); lastly, the Duke of York.

A Nobel Prize for Dr. Irving Langmuir

THE influence of the contributions to modern chemical thought of Dr. Irving Langmuir, who has been awarded the Nobel Prize for chemistry for 1932, is probably more widespread and generally appreciated than those of many of his predecessors. It was as if a new chapter had been commenced in the book of knowledge of the state and behaviour of molecules at interfaces, which forms the very bases of the science of colloids and is of fundamental importance in such diverse ramifications of the physical sciences as heterogeneous catalysis and thermionic emission, when Langmuir published his well-known papers in 1917. As occasionally happens, mathematical treatment may obscure the reality of physical and chemical processes, and that useful tool may prove an obstruction rather than an aid to further advance. It is no exaggeration to say that a new flood of light was thrown on the whole subject of the adsorption of, and reactions of, gases at solid surfaces, as well as the mechanism involved in changes in the surface tension of liquids. There are no better examples of the effects of welding our essentially chemical point of view, in which molecules are regarded as perfectly defined objects of definite form, with a physical appreciation of the general applicability of the Boltzmann distribution law and of the action of local fields of force extending over relatively short distances. This same breadth of treatment is also noted in the more recent and what some may regard as more physical aspects of his work. Thanks to Langmuir, thermionics is now an important branch of physical chemistry.

IT is only natural that investigations of such a fundamental character should have economic consequences, and Langmuir's work has led to many important industrial results, of which the gas-filled lamp is probably most widely appreciated. What was once "Dr. Whitney's experiment" in the General Electric Company has now become the life blood of all important industries, and it is a pity to note that apparently one large European firm is no longer encouraging fundamental research; probably the right men are not available. No small part of Langmuir's contributions to chemistry lies in his enthusiasm and the clarity of his presentation. The Lewis atom became as it were a household word when the concepts were developed, applied and expounded by Langmuir, and one almost had a vision of molecules of fatty acid floating across a water surface when listening to him. Those that know Langmuir as a friend are always impressed both by his kindness and his great breadth of interests. Whether it is ice-skating in winter, observing the formation of ripples and surface currents in summer on Lake George, or noting the brilliance of spiders' eyes when illuminated by a flash-lamp, there is always something of interest, something arresting and something which would convince many a classical scholar of the great advantages of science as an educational medium.

Retirement of Prof. E. B. Poulton, F.R.S.

WHEN, now forty years ago, Prof. E. B. Poulton succeeded Prof. Westwood, its first holder, in the Hope professorship of zoology at Oxford, great anticipations were entertained of the results to follow from the appointment of one who had already distinguished himself as an able investigator and experimenter in the field of evolutionary study. These expectations have been abundantly fulfilled; and it is not too much to say that under Prof. Poulton's untiring exertions, the Hope Department in the University of Oxford has become known throughout the scientific world as a chief centre for the maintenance and development of those views of organic evolution which owe their origin to the epoch-making work of Charles Darwin and Alfred Russel Wallace. Under his energetic administration, the great entomological collection, bequeathed by Mr. Hope and tended in its early days by the first Hope professor, has been immensely increased, and has been made available in an unexampled manner for the illustration of problems of first-rate biological importance. By his influence in stimulating and directing the efforts of observers and collectors in many parts of the world, Prof. Poulton has been able to accumulate a vast amount of material of the highest value for scientific workers at home, to whom he has never failed to afford the utmost help and encouragement. His own labours in the field of bionomics have been far-reaching and fruitful, and have caused him to be known everywhere as the most prominent living upholder of the doctrine of natural selection as propounded by Darwin in the "Origin of Species". His approaching retirement is felt, not only by entomologists, but also by the whole University of Oxford, as a serious loss; and it is much to be hoped that a successor may be found who will recognise and make it his business to carry on the great traditions of the Hope Department. It is a matter of congratulation that Prof. Poulton, when he relinquishes the engrossing task of administration, will be free to continue, on an even larger scale, those researches and expositions which have had so remarkable an influence on the progress of scientific entomology.

Dr. R. A. Millikan

IT is stated by Science Service, of Washington, D.C., that a Roosevelt Medal for achievement in science has been presented to Dr. Robert Andrews Millikan, director of the Norman Bridge Laboratory of Physics and chairman of the executive council of the California Institute of Technology. The presentation was made by James R. Garfield, Secretary of the Interior in the Roosevelt Cabinet. The medal is one of a series of awards established in 1923 by the Roosevelt Memorial Association. Usually three are given each year in three out of twelve fields of activity associated with Col. Roosevelt's career, but only one award has been made in 1932. Dr. Millikan has become widely known because of his achievements in physical research and was awarded the Nobel Prize for physics in 1923. Outstanding among his

accomplishments are the measuring of the charge on the electron and the study of cosmic radiation. Former recipients of the Roosevelt medal for work of a scientific nature include: Prof. Henry Fairfield Osborn, president of the American Museum of Natural History; Dr. Frank M. Chapman, curator of ornithology for the Museum; Dr. Herbert Putnam, librarian of Congress; and Richard E. Byrd, explorer.

Cambridge Philosophical Society

A BRILLIANT company assembled in the hall of Pembroke College, Cambridge, on Saturday, November 12, to celebrate by a dinner the centenary of the grant of a Royal Charter to the Cambridge Philosophical Society. Dr. A. Hutchinson, the Master of the College and president of the Society, was in the chair, and the occasion was honoured by the presence of H.R.H. Prince George. Among other distinguished people present were Mr. Stanley Baldwin, Chancellor of the University, the presidents of the Royal Society and of the British Association, and presidents or directors of many other leading scientific societies and institutions. The toast of the Society was proposed by Prince George and replied to by Dr. Hutchinson. The Master of Trinity proposed the toast of the guests, and responses were made by Mr. Baldwin and Sir William Bragg.

IN his reply to the toast of the Society, Dr. Hutchinson gave an interesting account of its origin and early work, and he was able to show that throughout its existence members of the Royal Family have honoured it by their favour and patronage. H.R.H. the Duke of Gloucester, a nephew of King George III and Chancellor of the University, accepted the office of patron on November 19, 1819, and made a handsome donation to the funds of the Society. Two years later H.R.H. Augustus Frederick, Duke of Sussex and a younger son of King George IV, became a vice-patron of the Society; afterwards he accepted the office of president of the Royal Society. When the Charter was granted by King William IV in 1832 he specifically confirmed his two kinsmen in their offices. The Prince Consort was patron of the Society when he was Chancellor of the University; and Dr. Hutchinson in the course of his speech said that he had been empowered by the Council of the Society to propose that the office of patron be revived, and that the present Chancellor, Mr. Baldwin, be invited to accept it. In his speech later in the evening, Mr. Baldwin stated that he regarded the office as one of high honour and accepted the invitation with pleasure.

Gaseous Combustion at High Pressure

AT the meeting of the Royal Society on November 10 when the Duke of York was admitted to the fellowship of the Society, Prof. W. A. Bone gave an account of Parts 14, 15 and 16 of his researches on gaseous combustion at high pressure. These record an exploration of the phenomena of explosion of hydrogen–air and carbon monoxide–air mixtures into regions of pressure much higher than those hitherto examined and the apparatus specially designed for the purpose was described. Hydrogen–air mixtures explode quite normally with initial pressures up to 500 atmospheres but at 750 atmospheres detonation occurs with violence sufficient to damage the apparatus. Carbon monoxide–air mixtures have been successfully exploded at initial pressures up to 1,000 atmospheres. As previously observed, the nitrogen is activated, absorbing during the early stages energy which is released during the later stages so as to retard the cooling of the products. This activated nitrogen reacts with excess oxygen, if present at the high temperature of explosion, giving oxides of nitrogen, the formation of which is favoured by increase of pressure. Nitric oxide dissociates readily during the process of cooling, so experiments were made in which the cooling is accelerated by causing the gas to expand suddenly at a predetermined instant after firing. Exploding mixtures of $(2CO + 3O_2 + 2N_2)$ at an initial pressure of 70 atmospheres, the yield of nitric oxide is 5·4 per cent, and results at 88 atmospheres indicate a probable maximum of about six per cent. Such yields exceed those previously recorded but are probably insufficient to serve as a basis for the commercial fixation of nitrogen by explosive combustion. Experiments were shown to demonstrate how a rise of pressure increases the luminosity of carbon monoxide–air flames and leads to the formation of oxides of nitrogen.

Heavy Oil Aeroplane Engine

THE Air Ministry has issued some particulars of the first British heavy oil aeroplane engine. The Rolls-Royce 'Condor' compression ignition engine has successfully passed an Air Ministry test of 50 hours, and flight tests are now being undertaken in a Hawker 'Horsley' aeroplane. The engine has been developed from the 'Condor' petrol aeroplane engine, which has been strengthened where necessary to take the increased forces due to the raising of the compression ratio from 6½ to 12½. The maximum explosion pressure within the cylinders is 800 lb. per square inch. At the normal speed of 1,900 revolutions per minute, the engine develops 500 brake horse power. The increase in weight over that of the petrol engine is less than ten per cent, the engine weight being 1,504 lb. or 3 lb. per brake horse power, a weight-power ratio which represents a very large reduction over that of the Beardmore 'Tornado' engines installed in the airship *R 101*. As a petrol engine, the Rolls-Royce 'Condor' has a weight-power ratio of approximately 2 lb. per brake horse power. Assuming that the fuel consumption of the heavy oil engine is twenty-five per cent less than that of the petrol engine, there should be a saving in the total weight of engine and fuel for a lengthy flight such as the present types of aeroplanes are capable of making. In addition, the experimental flight tests are intended to investigate the extent to which the size of the radiator and the weight of cooling water can be reduced as compared with standard petrol engines.

Plant Morphology

MR. H. HAMSHAW THOMAS's paper entitled "The Old Morphology and the New", read before the Linnean Society on November 10, created considerable interest. In recent years, Mr. Thomas said, a great gulf has arisen between the classical concepts of plant morphology and the new ideas which have been suggested by a study of the modern pteridophytes and of the older Palæozoic floras. A century of botanical investigation has not strengthened the foundations of the old morphology, but its modern exponents on the Continent have been led to regard much of what is termed morphology as irrelevant, and they reject all considerations of phylogeny, as well as the studies on the anatomy and cytology of plants. On the other hand, the foundations of the old system have been seriously shaken. Goethe, in a passage which has been generally overlooked, recognised the validity of some of the considerations of the new morphology, the name applied to the concepts put forward by Lignier, Bower, Tansley, and others. According to this view the body of the higher plants is derived from a thallus with forking branches bearing terminal sporangia; large leaves were derived from branch systems which may or may not have continued to bear sporangia. Thus the reproductive structures of the seed plants are to be considered as modified branches or branch systems rather than as modified foliar structures. The application of these ideas to the flowering plants may lead to considerable changes in our ideas of primitive characters. It is suggested that the flowering plants may be derived from the Palæozoic pteridosperms, and this leads to some new suggestions as to the morphology of modern floral structures.

Science and the Community

IN an address to the annual conjoint meeting of the Manchester Chemical Societies on November 10, Prof. A. Findlay, under the title "Science and the Community", strongly deprecated extravagant claims advanced as to the part science has to play in the administration of the State. Much disservice has been done to the cause of science by those who fail to recognise that scientific facts are often only one aspect or factor involved in a problem. Science is only one of the great human values, and attempts to antagonise the spirit of science and the quest of beauty, moral values and ethics are a misfortune to the whole community. Prof. Findlay suggested that, so far as industry is concerned, the battle for the recognition of science is already won, but his opinion that science has already received full recognition in the affairs of State was strongly challenged in the subsequent discussion. Prof. Findlay referred to the excessive specialisation of the average graduate in science and emphasised the need for a wider training and for the imparting of general culture and particularly the sense of values which the philosophy of science inculcates. In this, as in his plea for the recognition of the scientific spirit as one of the great expressions of the human spirit, making a contribution to spiritual welfare of mankind fully as important as that of art and literature and religion, Prof. Findlay presented an admirably balanced picture of the position of science in human culture which was greatly appreciated even by those who most strongly criticised either his assumptions as to the position of science in industry and the State, or the intractability of the human factors in social problems to the probings of the scientific mind.

Mexican Archæological Sites

THE Mexican Supreme Court has ruled, according to a Science Service (Washington, D.C.) message from Mexico City, that the country's archæological sites are under the jurisdiction of the Federal Government, and not that of the individual States. This settles an important issue, as has already been indicated in these columns (NATURE, Oct. 29, p. 656). Upheld by the recent decision, Federal Government archæologists arranged to proceed at once to make excavations at Monte Alban, where the spectacular discovery of a treasure tomb was reported last January. The expedition is under the leadership of Alfonso Caso, the discoverer of the Monte Alban tombs, and he will be assisted by a staff of four archæologists and six students. As little appears to have been known in Great Britain of the case upon which the Supreme Court has now pronounced until the matter was *sub judice*, a brief account of the point at issue and the origin of the dispute between the Federal Government and the States may not be out of place.

HITHERTO the Federal Government alone, with the exception of the State of Mexico, has shown any interest in the protection and investigation of the antiquities of early Mexican civilisation, the State governments being either indifferent, or without the resources necessary for such an undertaking. When, however, the remarkable treasures discovered in the Monte Alban tombs were placed on exhibition in March last, the enormous intrinsic value of the treasure and the wide-spread interest it aroused, which, it may be said, was responsible for the raising of a considerable sum of money from the public in the form of entrance fees, moved the State of Oaxaca, in which Monte Alban is situated, to lay claim to the treasure and to assert its rights over the antiquities within its borders. This at once raised the whole question of Federal and State jurisdiction in relation to antiquities, upon which the Supreme Court has now given its ruling. The decision has been awaited with anxiety, and there can be no doubt that the ruling is in the best interests of the study of Mexican archæology in present circumstances. The individual States have not the experience or the interest in their antiquities requisite for dealing with questions arising out of the granting of concessions for archæological exploration—a matter of importance in view of the widely-extended and invaluable activities of numerous expeditions from the United States now operating in Mexico; they have neither resources, nor personnel

for exploration, nor means for the proper display of archæological finds for scientific study as the Federal Government has; while it is generally thought among Mexican archæologists that, had the decision gone in favour of the States, as was expected, they would not have been able to afford their monuments adequate protection from damage, illicit exploitation and other dangers.

The West Indian Hurricane

THE reports of the hurricane that devastated a large part of Cuba on November 9 after destroying most of the banana crop in Jamaica and causing serious damage and loss of life in Little Cayman and Cayman Brac, show that this was the most destructive of the four storms that have caused much loss of life in the West Indies during the hurricane season that—since it is only once in about ten years that the season extends beyond October—should now be ending. The latest estimates give the loss of life in Cuba alone, due mainly to the sea wave on the south coast raised presumably by the southerly hurricane immediately to the east of the storm centre, as more than two thousand. The death roll was therefore much heavier than for the hurricanes which visited the neighbourhood of Galveston on August 13 last, and the Bahamas on September 5, and even for the very violent hurricane of September 26-27 in Puerto Rico. The most recent storm was abnormal in its track as well as in the late date of its occurrence. From information given in the *Times* of November 11, 12, and 14, it would appear that the centre was moving northwards or a little east of north when it passed to the west of Jamaica, and towards north-east when it crossed Cuba. Many storms pass the neighbourhood of Jamaica or the seas to the south of that island, but they are nearly always moving west or north-west, and, if they recurve to north-east, do so far away and in a much higher latitude. The hurricane season of 1932 will long be remembered, although when the total number of hurricanes in this season can be determined it will probably be found that, in the past fifty years, 1886 and 1887 with eleven storms in each case, still hold first place, while 1916, with a total of eight, remains outstanding in more recent years.

Optical Apparatus at the Science Museum

A SPECIAL exhibition dealing with optical phenomena and optical instruments will be opened at the Science Museum on November 19, and will remain on view until the middle of February, 1933. A special feature of the exhibition will be a number of demonstrations and experiments operable by visitors. These will illustrate reflection, refraction, dispersion, interference, diffraction, and polarisation of light as well as the working of simple optical instruments such as the telescope and microscope. They should be of particular interest to students, especially to those who have not the facilities for performing such experiments themselves. Other demonstrations will include a large projection microscope designed for the examination of metals in large pieces, a rangefinder specially adapted to take short ranges in the Museum, a home cinematograph projector using standard size film, a large ophthalmoscope for examination of the human eye and a modern epidiascope. The historical development of various optical instruments will be illustrated by examples selected from the Museum collections, and current practice in optical instrument manufacture will be further represented by a selection of modern instruments lent by various firms especially for the exhibition.

Exhibition of British Coastal Craft

A TEMPORARY exhibition illustrating the fishing boats and coastal craft of Great Britain will be opened in the Entrance Hall of the Science Museum on November 19 and will remain on view until the middle of February, 1933. Some thirty models which have been selected mainly from the large collection of small craft exhibited in Gallery 61 of the Museum, will be shown, in addition to a collection of about sixty photographic transparencies, some of boats for which no models are available in actual use, and others of detailed plans of the more important types. The arrangement will be geographical and will thus show in their proper relations the yoles and sexerns of the Shetlands and Orkneys, the fifies and baldies of the east coast of Scotland, and the cobbles of Yorkshire, together with the eighteenth century herring-busses and the early nineteenth century three-masted luggers which fished in the North Sea. East Anglia will be represented by the distinctive sailing drifters of Yarmouth, the trawlers of Lowestoft and also by the wherries and older keels of the Broads. There will also be the many craft peculiar to the Thames estuary, the barges, lighters and bawleys, besides the older wherries and peter-boats. From the south coast there will be examples of smacks from Ramsgate and Brixham, the eighteenth century hog-boats of Brighton and the luggers which have succeeded them; also the luggers of Penzance and of Fowey. Very little has yet been written about the west coast local shipping, but several typical examples will be included.

Shyok Glaciers and Indus Floods

UNDER the above title, Mr. J. M. Lacey in an article in the *Engineer* for October 14 gives an account of the formation of the great ice dams which form across the Upper Shyok River in Kashmir, and of the floods in the Indus valley which result from the release of the large volumes of water pent up behind the dams. The Upper Shyok has its source in the Rima Glacier in the Karakoram region, and in its downward course passes the three important glaciers, Chong Kumdan, 9 miles long, falling 3,000 ft.; the Kichik Kumdan, 7 miles long, falling 3,500 ft.; and the Aktash, 5 miles long, falling 2,000 ft. In the event of heavy accumulation of snow on the eastern range, these glaciers advance rapidly into the Shyok gorge. On occasions they flow right across the river until they strike the precipitous cliffs on the opposite side, and sometimes turn down the bed

of the river for hundreds of yards. The first recorded damming of the Shyok occurred in 1779, the water breaking through and causing a flood the following year. Since then the river has been dammed many times but experts find great difficulty in forming any conclusion regarding the periodicity of the advance and retreat of the glaciers. One observer, Major Mason, however, considers that after 1932 there will be no danger of a block for another thirty years.

Medical Uses of Radium

THE Medical Research Council has issued under the above title a summary of reports from research centres for 1931 on the radium treatment of cancer (Special Report Series, No. 174. London: H.M. Stationery Office. 1*s*. 3*d*. net). The main lines of radium therapy employed at present are described, and the results of the treatment of cancer of certain organs—tongue and mouth, breast, uterus, rectum, and others—are detailed. While the immediate results of the treatment are generally beneficial, the ultimate results are disappointing, few cases surviving after three or four years. But it must be remembered that most of the cases are advanced ones and inoperable. For these almost the only hope lies in radium therapy, and occasionally a striking result is obtained. Various methods of applying radium are being tested at the various centres, and we may hope in the future that improved methods will yield better results. A statistical analysis of all the cases treated at the Middlesex Hospital since 1925 is given in an appendix.

New Nature Reserve in Cheshire

AN addition of value has been made to the possessions of the Royal Society for the Protection of Birds in the Eastwood Nature Reserve, Stalybridge (*Bird Notes and News*, Autumn Number). The reserve, originally extending to about eight acres, was bequeathed by the Right Hon. John F. Cheetham, together with £5,000 for its upkeep. To this has been added an adjacent four acres, with £500, by a niece of the donor, Mrs. Wimbush of Taunton. The reserve is a beautiful ravine within the public park given by Mr. Cheetham to Stalybridge, and his wish that it should be kept in a natural state as regards fauna and flora will insure the continuance of a sample of wild Nature in the heart of an industrial area. Already there is abundance of wild plants and unexpected variety of birds, and judicious treatment of the reserve should add to the attractiveness of both.

Announcements

SIR ARTHUR KEITH, who is recovering from a serious illness, has been given six months' leave of absence by the Council of the Royal College of Surgeons of England. During his absence, the duties of conservator of the Museum of the College will be taken over by Mr. R. H. Burne, physiological curator to the Museum.

THE New Tank of the William Froude Laboratory at the National Physical Laboratory will be opened by the Right Hon. Stanley Baldwin on November 18 at three o'clock. Several demonstrations will be given at the opening ceremony, including screw propeller tests in the New Tank and rough water experiments in the Alfred Yarrow Tank.

A COURSE of lectures on "The Fear of Death in Primitive Religion" will be delivered by Sir James Frazer at University College, Gower Street, London, W.C.1, on November 25, November 29 and December 1, at 5 P.M. The lectures, although addressed to students of the University, will be open to others interested in the subject. Admission will be free and without ticket.

PROF. M. ISHIMOTO has been appointed director of the Earthquake Research Institute, Tokyo, in succession to Prof. K. Suyehiro, who died on April 9 of this year (see NATURE, 130, 132, 1932). Prof. Ishimoto is well known as the inventor of a tiltmeter, resembling Zöllner's horizontal pendulum, with which he has made many interesting observations on the tilts of the ground immediately preceding earthquakes.

AT the anniversary meeting of the Mineralogical Society held on November 1 the following officers were elected:—*President:* Sir John Flett; *Vice-Presidents:* Prof. C. Gilbert Cullis, Mr. Arthur Russell; *Treasurer:* Mr. F. N. Ashcroft; *General Secretary:* Mr. W. Campbell Smith; *Foreign Secretary:* Prof. A. Hutchinson; *Editor of the Journal:* Dr. L. J. Spencer.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in mathematics, mechanics and physics at the Polytechnic, Regent Street, London, W.1.—The Director of Education (Nov. 21). A joint examiner in mathematics for the Higher School Certificate Examination of the University of Bristol—The Registrar (Nov. 30). Two assistant civil engineers for the Directorate of Works, The War Office—The Under-Secretary of State (C.5.), The War Office, London, S.W.1 (Nov. 23). A public analyst to the Metropolitan Borough of Woolwich—The Town Clerk, Town Hall, Woolwich, S.E.18 (Dec. 2). A waterfowl research assistant at the National Institute of Poultry Husbandry—The Director, National Institute of Poultry Husbandry, Newport, Salop (Dec. 5). A laboratory steward in the Department of Zoology of the University of Bristol—The Registrar (Dec. 6). A secretary, assistant librarian and assistant curator of the Manx Museum—The Curator, Manx Museum, Douglas, Isle of Man (Dec. 7). A research fellow in bacteriology at the Lister Institute of Preventive Medicine—The Secretary, Lister Institute, Chelsea Bridge Road, London, S.W.1 (Dec. 9). An independent lecturer in applied mathematics at the University College of Wales, Aberystwyth—The Secretary (Feb. 1).

Letters to the Editor

Ultra-Violet Absorption Spectrum and Chemical Structure of Vitamin B_1

WE have been particularly interested in the report in NATURE[1] by Bowden and Snow regarding the photochemistry of the vitamins, in view of our investigations of the absorption spectra of various vitamin B_1 concentrates, a preliminary report of which was presented at the meeting of the American Chemical Society at Buffalo, September, 1931.[2] At that time we noted that the concentrates examined had absorption maxima at 2600 A., but as the concentrates were admittedly impure, and as some also presented maxima at other wave-lengths, we hesitated to identify any band with vitamin B_1.

In view of the possible presence of contaminating substances in the Jansen-Donath preparation used by Bowden and Snow, we agree with Morton and Heilbron[3] that their definite conclusion, "The correlation of the 2600 band with the activity of vitamin B_1 has thus been fully established" seems scarcely to have been justified by their reported experiment, in which irradiation of the preparation with the 2560 A. line reduced the intensity of the 2600 A. absorption band and destroyed the B_1 activity. Particularly is this true because, as we pointed out in our previous paper, certain biologically inactive purines and pyrimidines (which we have shown to be characterised by an absorption maximum at 2600 A., and to be destroyed by certain regions of the ultra-violet[4]), might be expected to contaminate B_1 concentrates. In view of this difficulty, we believed it advisable, at the time of our earlier report, to carry out parallel spectrographic and biological studies on a number of B_1 preparations before making positive statements about the absorption of the vitamin.

During the course of our later investigations, and prior to the publication of Bowden and Snow's report, Windaus and his co-workers[5] announced a crystalline B_1 preparation, believed by them to be pure B_1, which had, indeed, a pronounced absorption maximum at 2600 A.

Our later experiments include the comparison of the biological activity and ultra-violet absorption spectra of four B_1 concentrates prepared in this Laboratory, of three kindly supplied us by other workers, and of three reported by Guha[6] and by Windaus[5]. Full details of the spectrographic technique and biological assays will appear shortly in the *Bulletin of Basic Science Research*. The absorption curves of all these are presented in Fig. 1. The biological activity of three of these preparations (H_4, and the two Guha preparations) have not been determined by methods permitting comparison of their activities with those of the others.

In agreement with our previous suggestions, it was found that the two relatively inactive concentrates (H_1 and Cerecedo) had very high absorption in the 2600 A. region, presumably because of the presence of inactive purines or pyrimidines. When these were eliminated, a good degree of correlation was found between the activity and the absorption at 2600 A., better than that at any other wave-length in the ultra-violet spectrum. If, for example, the activity and the extinction at 2600 A. of the Windaus preparation are each taken as 100, these values are respectively, for the other four concentrates: Heyroth II, 26·7, 29·8; Seidell (30:85), 24·0, 32·8; Heyroth III, 6·7, 7·0; Seidell (30:182), 4·8, 14·4. This, together with the fact that a maximum at or near 2600 A. was found in all of the concentrates, indicated that vitamin B_1 is characterised by a 2600 A. band.

The type of absorption thus attributed to vitamin B_1 resembles most closely, of the nitrogenous heterocyclic compounds which have thus far been investigated, the absorption of pyrimidine-ring-containing compounds, or of compounds of the type of ergothioneine. The absorption curve of the sulphur-containing Windaus preparation, the most active of

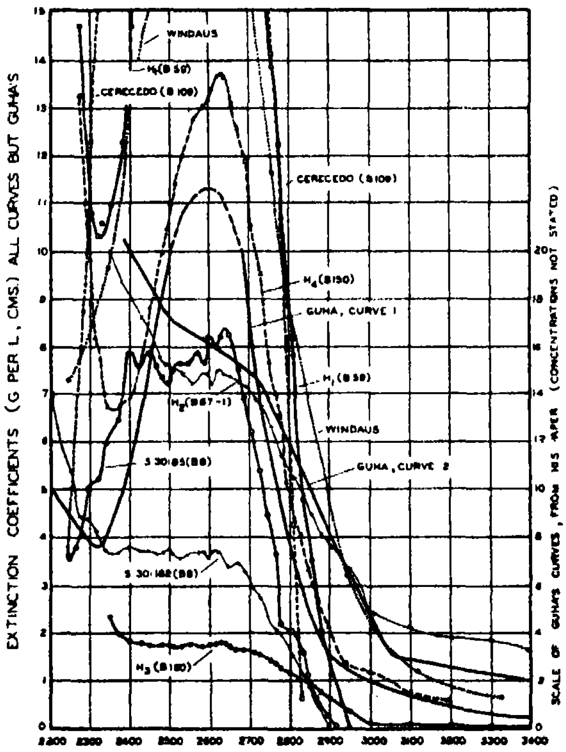

FIG. 1.—Ultra-violet absorption spectra of various vitamin B_1 concentrates.

those considered, is in fact very similar to that of uracil[4] or other pyrimidines. The molecular extinction coefficient of the Windaus preparation at 2600 A. as calculated from the empirical formula of Windaus is 8225, and as calculated from the formula of van Veen[7] is 8925. That of uracil at the same wave-length is 9500.[4]

[6] Guha, *Biochem. J.*, 25, 941; 1931.
[7] van Veen, *Rec. trav. Chim.*, 50, 200, 208, 610; 1931.

THE experiments of Heyroth and Loofbourow have established a close correlation between the physiological activity of concentrates of vitamin B_1 (after eliminating inactive purines and pyrimidines, which absorb in the same spectral region), and the intensity of the absorption band at 2600 A. They have thus provided a welcome confirmation of the proof which we gave in our letter to NATURE of May 14, that vitamin B_1 is characterised by an absorption covering the mercury line at 2537 A. The detection in their concentrates of inactive substances which absorb light of similar wave-length is of great value as a guide to the conditions under which the intensity of the band may be used as a measure of the concentration of the vitamin; but the identification of the characteristic band by the method of monochromatic irradiation was independent of the presence or absence of these impurities in the apparently homogeneous crystals which were used in our experiments.

In general, a molecule cannot be destroyed by light which it does not absorb. The only exception to this rule is provided by the phenomenon of photosensitisation. Thus, if light is absorbed by alien molecules of type A, giving rise to chemically active products, such as atoms of chlorine, it may happen that molecules of type B can be destroyed indirectly by the secondary chemical changes which these products are able to effect. This phenomenon, however, depends on a series of contingencies which we regard as unlikely, especially with so stable a vitamin. Moreover, an additional coincidence would be required to account for the parallel effects produced by irradiation and by the action of alkali, as described below.

If this indirect mechanism is excluded, the destruction of physiological activity which resulted from irradiation with the mercury line 2537 A. proves that light of this wave-length is absorbed selectively by the vitamin and that the absorption band at this wave-length is photochemically active.

The correlation of this band with the biological activity of the vitamin was confirmed by experiments in which both were destroyed by the action of alkali; but this action is less specific than that of monochromatic light, and was therefore cited only as collateral evidence in support of the more rigid proof which was made possible by the method of monochromatic irradiation.

Potency of Vitamin B_1 Preparations

RECENTLY (1932),[1] we have advanced indirect evidence for the belief that crystalline specimens of vitamin B_1 from baker's yeast, prepared by our methods, were more potent than those of Windaus, Tschesche *et al.* (1932).[2] Owing to their courtesy, we have been able to confirm this by direct test. Comparative tests upon pigeons (by curative method) have been made. As birds developed characteristic symptoms, they have been given alternately by mouth, approximately 14γ (0·014 mgm.) of each preparation. (Results by mouth are usually 30 per cent. lower than by injection.) The results were as follows:

Prep.	No. of birds	Dose given.	Average day dose	Standard error of mean	Vitamin B_1 units/mgm.*
G. (Windaus,					
Tschesche	10	14·2γ	4·81γ	0·63	279
et al.)	8	23·28γ	4·58γ	0·41	262
E. (our own)	10	13·8γ	2·56γ	0·35	469

The mean difference in potency $G:E$ is $1:1{\cdot}75$; that is, ours proved to be one and three quarter times as potent. Tested by the usual statistical formula, this difference would occur by chance less than once in fifty trials. It is supported by the tests upon larger doses, and also by reckoning the percentage cures with 14γ dose. For G we have 10/13 cured, and for E 10/10. As we have found it possible to fractionate our crystals still further, we have no hesitation in concluding that more potent vitamin B_1 can be prepared than preparation G, and that this cannot be therefore pure vitamin B_1.

A Growth-Stimulating Substance in Fatigued Muscle

MUSCULAR exercise results in development of the muscles concerned, and it influences other parts of the body. A metabolic product of muscular activity is probably responsible for the muscle hypertrophy, and it is possible that such a hormone may circulate in the blood and stimulate other organs. To our knowledge the only experimental study of this question is that of Bělehrádek[1], who fed tadpoles with artificially fatigued frog muscle. The weight of these tadpoles was increased by 28 per cent compared with controls fed on resting frog muscle, and they metamorphosed earlier than the controls. This has been confirmed by Siebert and Petow.[2]

We have extended this work by feeding blow-fly larvæ with frog muscle fatigued by electrical stimulation through the nerve. In 16 out of 18 experiments the larvæ fed on fatigued muscle grew larger than those fed on resting muscle, the average excess weight being 9 per cent. The larvæ fed on fatigued muscle did not metamorphose earlier than the controls, and their oxygen consumption was unchanged; but the rate of heart beat of the former exceeded that of the latter by 14 per cent.

Work is now being continued on the substances responsible for this growth stimulation and on their mode of action.

Limiting Mobilities of Some Monovalent Ions and the Dissociation Constant of Acetic Acid at 25°

VOGEL and Jeffery in a recent letter,[1] with the same heading as the above, have directed attention to the fact that we omitted, in our recent paper,[2] to mention that they have published[3] different figures from ours for the limiting mobilities of ions. Though we should, possibly, have referred to their work in that particular connexion, it was not ignored. The conductance measurements of these authors and the

discrepancies between their work and ours were discussed in a paper from this Laboratory.[4] This paper directs attention to the fact that Jeffery and Vogel used a bridge and cells which, due to parasitic currents, could readily give errors in the results. Their use of a water thermostat leads to additional errors of similar nature, as has been shown by Jones and Josephs.[5] Jeffery and Vogel have published conductance measurements only. To obtain ion conductances transference data are necessary. In their paper they present *two* sets of figures for the limiting ion conductances, leaving the choice to the reader. One set is based on a limiting transference number of potassium in potassium chloride of 0·497 and the other on a value of that constant of 0·490, the latter being the result of recent work in our Laboratory.

As to our results, the limiting conductance of the chloride ion, λ_{0Cl}, from which all the other limiting ion conductances may be computed, is based on measurements of conductance, *and transference numbers*, at a series of concentrations of four different chlorides (KCl, NaCl, LiCl, and HCl), and the same result $\lambda_{0Cl} = 76{\cdot}32$, within a few hundredths of a per cent is obtained from the data on each electrolyte. Previous workers have assumed validity of Kohlrausch's law of independent ion mobilities. We feel that our work has proved it, at least for these chlorides.

Our extrapolations have been made using a method based on the assumption that as the dilution is increased ion conductances will approach the relations derived by Onsager.[6]

Vogel and Jeffery also report an ionisation constant of $1{\cdot}776 \times 10^{-5}$ for acetic acid which, they point out, differs considerably from that published by MacInnes and Shedlovsky[7] who give $1{\cdot}753 \times 10^{-5}$ for that constant. We feel that it is sufficient to direct attention to the recent result of Harned and Ehlers[8] who, as the result of an extensive and careful investigation involving galvanic cells without liquid junctions, obtained the value $1{\cdot}754 \times 10^{-5}$ This check is particularly gratifying, since the methods used in the two researches are quite different.

Emission of Positive Ions from Cold Surfaces under the Influence of Strong Electric Fields

BEAMS[1] has brought forward experimental evidence showing that the application of a field of the order of 5×10^6 volts per cm. to a tungsten surface may result in the direct removal of adsorbed positive ions of the alkali metals. Ianitsky[2] had previously described experiments in which such an effect was obtained with fields about a hundred times smaller, the positive ions concerned being those of the permanent gases.

I have recently been led to investigate the fluorescence of the glass in a hot cathode X-ray tube,[3] and found that the most negative part of the glass occasionally showed fluorescent spots, which must therefore have been due to positive ion bombardment. The phenomenon was observed with the filament switched off, the gas pressure less than 2×10^{-6} mm. of Hg, and only 20 k.v. across the tube. A detailed consideration of possible mechanisms of formation of the positive ions eliminated all but one, namely, their removal from an adsorbed layer of impurity on the anode. This confirms the observations of Ianitsky, who however did not observe the positive ions as such but by the resulting change in gas pressure.

Ianitsky suggested that the adsorbed gas layer normally exists in a partially ionised form, so that the phenomenon observed by him and by myself would be fundamentally the same as that observed by Beams. It seems to me more probable, however, that it was fundamentally different, the gas layer being *first* ionised by X-rays or by electrons (which would have inevitably been present in the experiments), and *then* the ions removed by the field. Since some of the ions would be formed at a distance of several atomic radii from the surface, a much smaller field would suffice for their removal than was required in Beams's experiments with degassed surfaces. This agrees with experiment.

It seems, however, likely that the compound effect was present in the experiments Beams carried out on gas layers. If this was so, the observed critical voltage for the effect to occur was either that for the positive ion emission or that for starting the discharge responsible for the ionisation, whichever was the larger of the two.

Origin of Zero-Point Entropy

EUCKEN and his collaborators have pointed out that the failure of Nernst's heat theorem—the so-called third law of thermodynamics—which occurs in some cases, is due to the zero-point entropy[1]. A definite zero-point entropy arises from the existence of 'frozen-in' phases stable at higher temperatures which do not reach the real thermal equilibrium on cooling to the neighbourhood of the absolute zero. Teske and I, for example, have found that solid carbon monoxide near 10°K. exhibits such a state in spite of its crystalline structure[2]. Clayton and Giauque have confirmed this result[3] and explained the discrepancy by the suggestion that the asymmetry of the carbon monoxide molecule gives rise to two positions in the lattice of nearly equal energy. The formation of a fully ordered crystal is thus prevented. No such effect is to be expected in the case of nitrogen, which is a symmetrical molecule. Dr. Teller has directed my attention to the fact that similar behaviour may be shown by nitrous oxide as opposed to the symmetrical carbon dioxide: this has proved to be true.

The following table gives some zero-point entropies calculated from the difference of the direct thermal measurements and the entropy value from band spectroscopic data. If the disarrangement is

complete, the basic probability is 2 instead of 1 as in a perfect crystal and the resulting entropy would be

$$R \ln 2 = 1 \cdot 38 \text{ units as maximum.}$$

Molecule	Zero-point entropy	Author
$N = N$	$-0 \cdot 07 \pm 0 \cdot 20 \sim 0$	Eucken, 1929.[1]
$O = C = O$	$+0 \cdot 32 \pm 0 \cdot 27 \sim 0$	Eucken, 1929.[1]
$C = O$	$+1 \cdot 06 \pm 0 \cdot 25$	Clusius and Teske, 1929.[2]
	$+1 \cdot 12 \pm 0 \cdot 10$	Clayton and Giauque.[3]
$N = N = O$	$+0 \cdot 90 \pm 0 \cdot 32$	Clusius, Vaughen and Hiller, 1930.[4]
$N = O$	$+0 \cdot 75 \pm 0 \cdot 10$	Johnston and Giauque, 1929.[5]

The values of Giauque and his collaborators are explicitly given by these authors. The other data are calculated from the difference of the vapour pressure constant and the chemical constant. The latter has been found by using the value $59 \cdot 4 \times 10^{-40}$ C.G.S. units for the momentum of inertia for nitrous oxide and $70 \cdot 8 \times 10^{-40}$ C.G.S. units for the same quantity for carbon dioxide.[6]

The symmetrical molecules nitrogen and carbon dioxide show no appreciable effect, while the asymmetric carbon monoxide, nitrous oxide and nitric oxide show a definite discrepancy of the same sign, order of magnitude and presumably the same origin.

In conclusion, Nernst's theorem does not apply to structures composed of asymmetric molecules held in position in the lattice by relatively weak orientational forces. We intend to investigate in this laboratory other asymmetric molecules and the possibility of more complete arrangement at liquid helium temperatures. Otherwise it is to be expected that the residual entropy will diminish with increasing molecular asymmetry.

Eddington's Theory and Physical Constants

EDDINGTON'S[1] equation for the mass of proton or electron

$$10m^2 - 136m + 1 = 0 \quad (1)$$

holds only for 'very mild' interaction between the elementary charges. It has been extended for interactions at intra-atomic distances and the equation comes out to be

$$10m^2 - 135m + 1 = 0 \quad (2)$$

The 'free' mass from (1) and 'singly constrained' mass from (2) give two values of e/m in perfect agreement with the deflection and the spectroscopic values respectively. For intra-atomic problems the latter alone is applicable. By using Eddington's[1] relation $ch/2\pi e^2 = 137$ and the precise values for the Rydberg number for hydrogen (H_1) [2], Faraday's constant[2], the velocity of light[2] and the chemical atomic weight of monoprotonic hydrogen, from Bleakney's $H_1 : H_2$ ratio[2,3] the following precision values are obtained.

Chemical atomic weight of monoprotonic hydrogen .	$H_1 = 1 \cdot 00774$	$\pm 0 \cdot 00002$
Rydberg number for infinite mass	$R = 109737 \cdot 516$	$\pm 0 \cdot 050$
Specific charge of free electrons	$e/m_0 = 1 \cdot 77001$	$\pm 0 \cdot 00013 \times 10^7$ e.m.u.
Specific charge of singly-bound electrons . . .	$e/m_1 = 1 \cdot 75697$	$\pm 0 \cdot 00013 \times 10^7$ e.m.u.
Electronic charge . . .	$e = 4 \cdot 81209$	$\pm 0 \cdot 00037 \times 10^{-10}$ e.s.u.
Avogadro's number . . .	$N = 6 \cdot 01132$	$\pm 0 \cdot 00089 \times 10^{23}$
Planck's constant . . .	$h = 6 \cdot 64879$	$\pm 0 \cdot 00102 \times 10^{-27}$
Compton shift for free electrons at 90° . . .	$h/m_0c = 0 \cdot 0244557$	$\pm 0 \cdot 0000003 \times 10^{-8}$ cm.
Compton shift for singly-bound electrons at 90°	$h/m_1c = 0 \cdot 0242758$	$\pm 0 \cdot 0000003 \times 10^{-8}$ cm.
Wave-length of molybdenum $K\alpha_1$, line	$= 0 \cdot 709701$	$\pm 0 \cdot 000016 \times 10^{-8}$ cm.
Calcite grating space (Yuching Tu's crystal) .	$= 3 \cdot 03749$	$\pm 0 \cdot 00048 \times 10^{-8}$ cm.
Wien's radiation constant .	$hc/k = 1 \cdot 44128$	$\pm 0 \cdot 00013$
Stefan's radiation constant .	$= 5 \cdot 65050$	$\pm 0 \cdot 00051 \times 10^{-5}$

Perry and Chaffee's[4] and Kirchner's[5] determinations of e/m have been analysed. Systematic errors in the method, procedure and apparatus have been found which account for a correction of more than $+0 \cdot 8$ per cent. So far as the corrections are determinable, calculations from both the data give the value $1 \cdot 770 \times 10^7$ in agreement with the e/m_0 value given above and not $1 \cdot 760 \times 10^7$.

Millikan's[6] value for e has been analysed and found to require a correction, due to the holes in the top plate of his condenser, amounting nearly to $+0 \cdot 8$ per cent. The values got by direct measurement of charge on α-rays by Braddick and Cave[7] and Ward, Wynne Williams and Cave[8] give a value in agreement with the above. Also the discrepancy between grating and crystal values of X-ray wavelengths has been removed by the above, without calling into account the hypothetical mosaic structure suggested by Zwicky[9] against which there is already so much evidence, at least in the X-ray measurements.

The criticisms of Birge[2,10] against $ch/2\pi e^2 = 137$ have been analysed and found to disappear completely on using the corrected values of e and e/m'.

A detailed discussion will be published early.

Occurrence of *Lithothamnion* in the South Indian Cretaceous

IN two previous communications[1] one of us reported the discovery of abundant algæ, chiefly *Lithothamnion*, in some of the limestones of Upper Cretaceous age from the Trichinopoly and Pondicherry areas of South India.

In the course of a recent examination of the limestone ridges near Cullygoody (Trichinopoly Cretaceous area) we have collected a number of specimens of a pebbly or conglomeratic rock, which is often found at the base of these limestones. In hand specimens, this rock shows a number of rounded or oval cream-coloured 'pebbles' and presents an appearance very similar to the pebbly character of some of the Niniyur flints and cherts.[2] A micro-

scopic examination of this pebbly rock has also revealed the occurrence of abundant *Lithothamnion* of which at least three different kinds seem to be recognisable—all the 'pebbles' being seen as nothing but patches of algæ.

We consider the occurrence of these algæ in the Cullygoody limestone as of great importance since they belong to a period even earlier than that represented by the Niniyur flints and limestones. Whereas the latter represent the topmost sub-division of the Trichinopoly Cretaceous, corresponding to the Danian of the European stratigraphical scale, the Cullygoody limestone is a member of the lowermost sub-division—the Utatur stage—which is equivalent to the European Cenomanian.

From the evidence now available it is thus obvious that not only were the algæ abundantly present during the Cretaceous period in India, but also that they have been one of the most important limestone builders in the upper Cretaceous seas of Southern India.

Diploidisation of Haploid by Diploid Mycelium of *Puccinia helianthi* Schw.

THE interaction of two haploid cells of opposite sex to produce the diplophase is a phenomenon well known in heterothallic species of the Hymenomycetes and of the smut and rust fungi. Buller[1] has recently shown that a diploid mycelium of *Coprinus lagopus*, on coming into contact with a haploid mycelium of that species, transforms the latter mycelium into the diploid condition. He has introduced the word *diploidisation* "to designate in the Hymenomycetes the process by which a haploid cell, or mycelium, is converted into a diploid cell, or mycelium, by the formation of conjugate nuclei within the cell or mycelium". An extension of the application of this term to designate a similar process in other groups of the Basidiomycetes, such as the smuts and rusts, does not appear inappropriate.

Craigie[2] found that *Puccinia helianthi* Schw. is heterothallic. His experiments showed that the diploid, or æcial, stage could be produced by allowing two haploid pustules of opposite sex to coalesce, or by applying the pycnospore-containing nectar of a haploid pustule of one sex to a similar pustule of opposite sex. Experiments which I have recently carried out show that diploidisation of a haploid mycelium of this rust also occurs when it comes into contact with a diploid mycelium. This phenomenon may very probably be found to occur in other heterothallic eu-autoecious rusts.

Sporidia of *P. helianthi* were sown sparsely on the upper surface of the first two foliage leaves of sunflower seedlings (*Helianthus annuus* L.). From these inoculations there arose forty-nine haploid pustules.

When three weeks old, none of these pustules bore æcia. Twelve of them were then marked, to serve as controls; and beside sixteen others, at a point just beyond the periphery of each, urediniospores of *P. helianthi* were sown. A week later urediniospores were sown similarly beside twelve other pustules; and, a week later still, a sowing of urediniospores was made beside the remaining pustules.

As a result of these inoculations, uredinia (diploid pustules) arose at, or very near to, the margin of each of the thirty-seven haploid pustules. Thus diploid mycelium grew in juxtaposition to haploid mycelium.

From eight to twelve days after the inoculations with urediniospores were made, æcia began to appear on the under side of all the thirty-seven pustules. Usually the æcia first appeared in that part of a pustule lying nearest to the uredinial pustules, and later in the parts more remote (Fig. 1). In a few pustules, the first æcia to appear arose rather irregularly spaced over the whole under-surface of each. No æcia appeared in any of the control pustules.

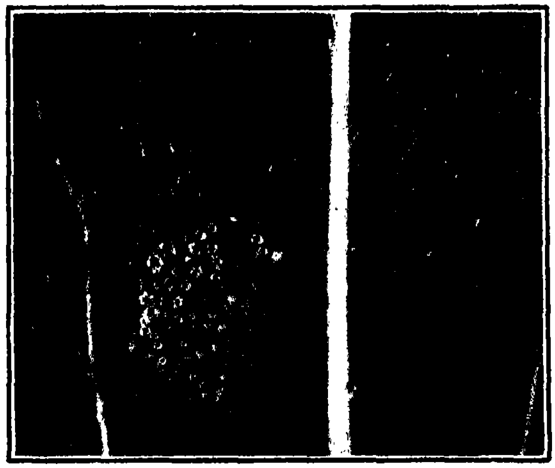

FIG. 1.—The under surface of a part of a sunflower leaf showing a monosporidial (haploid) pustule of *Puccinia helianthi* in which has occurred diploidisation by uredinial (diploid) pustules of that rust. Æcia have appeared at the side of the monosporidial pustule adjoining the uredinial pustules. The photograph was taken fourteen days after the leaf was inoculated with urediniospores, at which time the monosporidial pustule was thirty days old. × 4·5.

A cytological examination of the pustules which produced æcia has not been made, but it is assumed on the basis of these experiments that, when contact between a haploid and a diploid mycelium of *P. helianthi* is established, the diploidisation of the haploid mycelium is effected by successive nuclear divisions and migrations, as has been described by Buller[1] for *C. lagopus*.

Helium Content of Beryllium

THE abnormally high helium content of several Palæozoic beryls discovered by Strutt[1] has recently been verified by Paneth and Guenther.[2] Atkinson and Houttermans have discussed[3] the proton bombardment in the interior of the stars and the possible formation of Be^8 which being probably unstable would yield two helium nuclei, and Lord Rayleigh[4] suggests that the

high helium content of beryls might conceivably be due to Be^8 which has existed in geological times even if not known to exist at present. This implies, however, that Be^8 existed at least in Palæozoic times, a relatively very late period since the star state and proton bombardment. The recent experiments of Cockcroft and Walton[5] would indicate that Be^8 can have only a very short life period. A possible source of excess helium might be found, however, in the following proposed mechanism:

$$Be^9 + \alpha\text{-particle} = 3 \text{ He nuclei} + \text{neutron},$$

and treating this in a similar manner to Chadwick's treatment,[6] the maximum energy of the emission of the neutron is about $5 \cdot 2 \times 10^6$ electron volts as compared to $5 \cdot 7 \times 10^6$ found in Chadwick's experiments and a maximum energy of about 8×10^6 electron volts given by the equation assuming C^{12} is the end product. If both mechanisms are possible we might then expect two groups of neutrons of different maximum energies. In the Palæozoic beryl, about 300×10^6 years old, radium was detected but no thorium. The α-particle of greatest kinetic energy is therefore from Ra C′ which would give a maximum energy to the neutron of about $7 \cdot 7 \times 10^6$ volts or about $10 \cdot 5 \times 10^6$ if C^{12} is the end product.

Even if every α-particle is effective, however, a maximum of only three times the helium produced by the radioactive integration can be expected. The contribution to the helium which is to be expected from the work of N. Feather,[7] in which it is shown possible to free an α-particle by neutron bombardment of nitrogen or possibly some other element, contained in the mineral, can only be a small fraction of the radioactive helium, since only one neutron is formed from each effective α-particle and but a small fraction of these cause disintegration. Moreover, the sequence of events by which a neutron ejects a proton in the mass of the beryl and this in turn builds Be^8 which breaks down into two α-particles is so unlikely as not to come into consideration at all in accounting for the excess helium.

All the above possible mechanisms are, therefore, insufficient to account for the excess helium in the beryls such as from Chester, Penn., U.S.A., containing $0 \cdot 19 \times 10^{-2}$ gm. uranium which would generate approximately $0 \cdot 065$ c.c. of helium in 300×10^6 years, a reasonable lapse of time since the Palæozoic age, compared to the experimentally determined value of at least $0 \cdot 68$ c.c.

Nevertheless, such possible sources of extraneous helium must be considered when determining geological age by the helium ratio, especially when the lighter elements are in abundance.

Natural Melody

IN his letter in NATURE of November 5 on "Natural Melody" Sir Richard Paget inquires whether such an effect can have been produced in Nature, as, for example, by a broken bamboo stem. The following extract from Godinho de Eredia's "Report on the Golden Chersonese": 1597–1600 (English translation by Mr. J. V. Mills of the Malayan Civil Service) may be of interest, though it concerns speech, not melody:

"To conclude entirely with the Peninsula, I will relate a curious phenomenon which occurs at the mouth and entrance of the River Panagim [now called the River Linggi. J.B.S.]: here there are dense thickets of Bamboos, and among them are two very tall stout Bamboos which are set in such a manner that one of them towers over the other; now it is an actual fact that by day and by night human voices are heard proceeding from these Bamboos; one of them says '*Suda*', that is to say, '*Enough*', and the other replies '*Bolon*', which is as much as to say '*Not yet*'.

"I always regarded this as a worthless fairy-tale, until Affonso Vicente, Ambassador to Achem, assured me that he personally heard these voices saying '*suda*', '*bolon*', when he went to this place on the Panagim for the sole purpose of observing this most curious occurrence in the year 1595."

An Epithelial Tumour of the Intestine of a Frog

THE following report is made because a similar pathological condition has not previously come to my attention. The frog, *Rana pipiens*, was brought to the laboratory from the frog tanks with a number of others for the use of students. There was nothing in its external appearance to indicate any abnormality. It seemed as well nourished as any. When the abdomen was opened it was found to be nearly filled with an irregularly cubical mass, the liver was much compressed and only about two centimetres of intestine could be found. In colour the mass was pale yellowish brown; its consistency varied, some parts being quite firm to the touch and others cystic. On section, tubular openings coursing irregularly through the mass were disclosed, and where these were near the surface they gave the impression of a cyst when palpated. These tubes appeared to be the missing intestine. The entire specimen was submitted to the Department of Pathology, which reported as follows:

"Large yellowish tumour mass occupying main part of abdomen of frog, with a lumen suggesting intestine.

"Section shows tumour to be of epithelial origin; the cells are arranged in irregular acini suggesting a tumour arising from intestine.

"Epithelial tumour."

It is remarkable that the frog could have lived in spite of the interference with digestion and absorption that would seem inevitable from the presence of so large a mass in the abdomen, and especially of one involving the intestine to so great an extent. Inspection and handling of the voluntary muscles did not reveal any atrophy. I shall be much interested to hear from anyone who has observed a similar condition, and should like to secure all the information possible as to the frequency of occurrence, rate of growth, and effect on health and length of life.

Research Items

Precious Stones in Medieval Folklore.—Dr. J. P. Heather has made a study of the references to precious stones in the middle-English verse of the fourteenth century, comparing these with the treatment of the subject in the Anglo-Norman lapidaries (*Folk-lore*, vol. 42, pt. 3). Although precious stones are connected with animals on many occasions in the verse, especially as similes, reference to the belief, common in the lapidaries, that precious stones were found in the heads of animals, such as toads, vultures, crabs, practically do not occur; yet their frequency in later literature suggests that they were well known among the people. In another direction, stones were connected with Nature. In the works of the poet Gower each of the fifteen stars has its herb and its precious stone, and stones are enumerated as set in the crown of the sun. The first three, Lieuchis, Astrices and Ceramius, "no persone hath upon erthe". Six of the remainder—crystal, adamant, smaragdine, elitropius, jaspis and jacinthus—are well known; but ydriades and dendides are not traceable in the lapidaries. Precious stones have their effect on both men and women in regard to their qualities and character, while some improve their moral qualities. Other stones confer invisibility, or invincibility in combat, or eloquence, and so forth. In virtue of a hyacinth engraved with a figure, half woman and half fish, set in fine gold, covered with wax and held in the fist, "you will be seen of no man". The property of a stone to which reference is made most frequently in verse is that of shining with its own, and not reflected light, this quite overshadowing the magical property, though the latter is well known. Thus the carbuncle in "The Romaunt of the Rose" gives forth a light at night by which "men mighte seen to go, for nede, a myle or two, in lengthe and brede". References to the healing power of the stones are not frequent, though there is abundant evidence that it did exist. In regard to use, reference is most frequent in relation to burial rites.

The State in Ancient India.—The concept of the State in ancient India and the sphere of State-action, topics upon which there is much difference of opinion among European and Indian scholars, is discussed by R. Pratapagiri in the *Journal of the University of Bombay*, vol. 1, pt. 1. The end of the State is to maintain *dharma*, upon which the security and prosperity of the realm depend. The different orders and castes are to be strictly confined to their appointed functions and it is the duty of the king both to protect the four orders in the performance of these functions and to see that they carry them out. Otherwise the State would dissolve into mutually repellent atoms. Further, it is the duty of the king to lead back into the right path any who stray from the rules of their caste or order. The king not only could, but also should, interfere in the most private relationships of life. The only limits to the power of the State are of a theocratic nature. It is the duty of the king to protect the sacred groves and the castes and orders engaged in religious observance. By this protection and restriction he increases the *dharma* in his realm. He is therefore the root of *dharma*. It follows that the ancient Indian State is of the autocratic type and highly centralised, the king being executive, administrative and legislative head, as well as military leader, guiding and controlling the religious, moral and social life of his people. Hence when imperial government was established, and especially under the Mauryan monarchs, the growth of the king's authority led to the establishment of councils and a bureaucratic system which usurped the place of the ancient meetings of the folk. The kingship was not a constitutional institution limited by checks, as some think, but an autocracy of which the only limitation was its end—the maintenance of *dharma*.

Characteristics of Geographical Races of Beetles.—While the geographical variations of morphological characters within a species have been extensively studied, practically no work has been done on the physiological differences between geographical races. A recent paper by Krumbiegel on the races of the beetle *Carabus nemoralis* (*Zoolog. Jahrb., Systematik*, 63, 1932) is largely physiological in its outlook and methods and deserves, therefore, special attention. Temperature reactions of various geographical races of the beetle have proved to be in direct correlation with the climatic conditions of the respective areas of their occurrence. Positive reactions to light increased in their regularity and intensity when a series of races ranging from north European to the Mediterranean were examined. These physiological characteristics were found to change gradually from north to south. Particularly interesting is the fact that two races from widely distant areas can differ physiologically just as much as two distinct species, while morphologically they are clearly conspecific. Moreover, the races which can be easily separated by their reactions towards light are often almost identical morphologically. An exact morphological analysis, however, revealed differences between them, namely, in the shape of the eyes and in their structure.

Control of the Citrus Black Fly in Jamaica.—The citrus black fly (*Aleurocanthus woglumi* Ash.) is one of the major pests affecting citrus trees in Jamaica. The control of this insect by the use of insecticides presents great difficulties, especially as citrus trees in Jamaica are rarely cultivated in regular groves, but are scattered among other trees which also harbour the pest. The question of its control by biological means is discussed by Mr. W. H. Edwards, the Government entomologist, in *Entomological Bulletin* No. 6 (1932) of the Jamaica Department of Science and Agriculture. The recent introduction of the Chalcid parasite, *Eretmocerus serius* Silv., for the purpose of attempting to control the citrus black fly in Cuba, has been attended by remarkable results, since this pest seems to have been eradicated in regions where the parasite was liberated. This outcome naturally suggested trial of the same experiment in Jamaica and supplies of parasitised black fly nymphs were sent by Dr. J. G. Myers from Cuba. Mr. Edwards states that the breeding out of these parasites from the material thus obtained has been successful and that liberations have already taken place in three selected localities. While it is premature to assert whether the parasites will establish themselves under these

new environmental conditions, as successfully as they have done in Cuba, there is every reason to believe that they will do so. If the expected result follows, the introduction should prove of immense benefit to the Jamaican citrus-growing industry.

A New Species of *Coeloplana*.—A single specimen of *Coeloplana metschnikowii* was discovered in the Red Sea and described in 1880, and no other species, indeed no other specimen, was recorded until 1902 when Abbott gave an account of two new species from Misaki, Japan. Since then seven other species have been described, namely, two more from Misaki, two from Annam, two from French Indo-China and one from Amboina. The latest of the four species from Misaki is *C. echinicola* described by H. Tanaka (*Mem. Coll. Sci.*, Kyoto Imp. Univ., ser. B, vol. 7, No. 5, Art. 12, 1932) who obtained specimens on the test of a sea-urchin, *Toxopneustes pileolus*. This species is distinguished by its coloration and by the large number (thirty-two, eight larger and twenty-four smaller) of its dorsal processes. The author states that asexual reproduction by means of laceration occurs especially during the night in early summer. One fairly large individual produced more than ten lacerated pieces in a week but this process ceased after the middle of August and in September this *Coeloplana* disappeared entirely from the littoral zone. In another paper (Art. 11) in the same journal the author gives an account of re-organisation in regenerating pieces of *Coeloplana*.

New Thermophilic Organisms.—During the summer of 1930, Dr. E. Hindle visited the thermal springs at Bax, near Bordeaux, and on the surface of the pool of hot water in the market place noticed a floating scum of organic matter, consisting of blue-green algæ and other filamentous organisms, some of which he collected and brought back for examination (*J. Roy. Micr. Soc.*, vol. 52, pt. 2, 1932). When examined four weeks later, the only obvious living organisms were bacteria, but as the temperature of the thermal pool was about 54° C., some of the material was incubated in boiled tap-water at this temperature for one or two weeks and a variety of micro-organisms developed in the liquid, including at least two groups of which there is only one previous record of their active life at such high temperatures. At least two species of amœbæ were observed in the cultures, one comparatively large, 20–30μ in diameter, the other smaller and probably, from its structure and the absence of any flagellate phase, belonging to the genus *Hartmannella*. The larger species soon died out but the *Hartmannella* has been cultivated and found to be very susceptible to slight alterations in temperature. In spite of abundant growth at 53°–54° C. for nearly a year, all attempts to raise the temperature at which the species would grow by even 1° C. gave negative results; when the temperature was so raised all active forms quickly disappeared. Encysted forms were unaffected and when grown again at 54° C. active amœbæ resulted. The cysts withstand temperatures ranging from below 0° C. to at least 60° C. and dried cysts kept in an unheated shed were found to be alive ten months later. The original material from Bax, when reheated at 54° C., also showed the presence of spirochætes identical with those commonly found in rivers and pools; these thermophilic races have probably been derived from individuals to which such high temperatures would be rapidly fatal.

Bud Mutation in *Ficus*.—Mr. K. P. Biswas, curator of the Herbarium, Royal Botanic Garden, Calcutta, reports an interesting bud mutation on one of the branches of a tree of *Ficus Krishnæ* DC., which has been growing in the nursery of the Garden for thirty-two years. *Ficus Krishnæ* itself is a species of uncertain status and origin. Only ten per cent of the seed breed true, the other ninety per cent give *Ficus Bengalensis* L. The plant was named by C. de Candolle in 1901, but the Indian view is that it is a garden variety of *F. Bengalensis*, and Prof. Molisch when visiting Calcutta in 1929 also considered it a mutation of this species. A bud mutation now developed in the Botanic Garden has broad flat leaves like the leaves of *F. Bengalensis*, and suggests that *F. Krishnæ* may prove to be a chimæra with a core of *F. Bengalensis*. Dr. S. Hidayetulla has taken up the study of the genetics and cytology of this species.

Surveys in South Georgia.—The highly indented coastline of South Georgia affords numerous harbours and anchorages, many of which have been used and roughly surveyed by whalers and exploring expeditions, but most were not accurately charted until the "Discovery" expedition took the work in hand. The results of this work, during such time as was available in the seasons 1926–27, 1928–29 and 1929–30, is now published in the "Narrative of Hydrographic Survey Observations in South Georgia and the South Shetland Islands, 1926–1930, by Lieut.-Comdr. J. M. Chaplin, R.N. (*Discovery Reports*, Vol. 3, pp. 297–344). Some of the work was done in R.R.S. *Discovery* and S.S. *William Scoresby*, but most in a motor-boat. Altogether 357 miles of coast-line were surveyed under conditions of no small difficulty, since on about one day in four the weather prevented work being done. All the harbours were hydrographically surveyed in addition. The volume includes reproductions of the Admiralty charts on which the surveys appear. The work in the South Shetlands was very limited and in the South Orkneys was confined to Borge Bay on Singy Island, which is also known to the whalers as Bruce Bay. In the South Orkneys, practically all the coast-line of Coronation Island needs to be re-surveyed, and in the South Shetlands many corrections will have to be made to charts. Among the photographs reproduced in this volume is a striking one of a discoloured iceberg which shows how ice may be taken for land and explains some of the erroneous landfalls of polar regions.

Schuster-Smith Magnetometer at Helwan.—Continuous terrestrial magnetic registration has now been in progress at Helwan, Egypt, for twenty-four years, and data of great value have been accumulated (though unfortunately the hourly values have not been published). The absolute values of the horizontal and vertical force have been derived hitherto from a Kew magnetometer, but recently the instrumental equipment of the Observatory has been greatly improved by the installation of a Schuster-Smith magnetometer. This is a copy, on a slightly smaller scale, of the original instrument designed at the National Physical Laboratory, with certain improvements. Its constants have not been determined by measuring the dimensions of the coil, but have been obtained by comparison with the standard Schuster-Smith magnetometer at Abinger. Its great advantage is the speed and accuracy of the measures which it

affords. Comparisons of its determinations with those simultaneously made with the Kew magnetometer, over a period of five months, are reported on in Bulletin No. 35 (Cairo, 1932) of the Helwan Observatory; they disclose a difference of about 30γ between the two sets of measures. From January 1, 1932, the new instrument is to be adopted as the Helwan standard instrument.

A Centrifugal Machine for Examining the Adhesion of Layers of Lubricant to Metallic Surfaces.—In a paper read before the Institution of Petroleum Technologists, W. F. Parish and L. Cammen describe a high-speed centrifugal machine, built on the lines of the Sperry gyroscope, and capable of being rotated without appreciable vibration up to speeds of 18,000 revolutions per minute. An oil film present on the rotor of this machine is thrown off in stages, as the speed of rotation is increased. The first portions to fly off are those constituting the thick film responsible for the 'complete' or 'film' lubrication, in which the laws of hydrodynamics hold good. The outer portions of this layer are torn off fairly easily, the inner portions less so, the adhesion to the metal apparently increasing on passing from the exterior to the interior of this fluid film. Possibly the intensity of the attraction to the metal varies as the inverse square of the distance in this region. When the whole of this outer film has been thrown off, there still remains a layer of oil, termed the 'Langmuir' layer, which is many molecules thick, and can be wiped off by a piece of paper. It cannot, however, be thrown off by centrifugal force, until speeds many thousands of revolutions greater than those needed to remove the whole of the 'Coulomb Law' or loosely attached layer are reached. When this 'Langmuir' layer has been removed by wiping, further centrifuging causes a fresh, very similar layer of oil to appear, almost certainly by extrusion of oil occluded in very fine cracks in the metallic rotor. Several such films can be reconstructed from the occluded oil, after wiping off each film in succession after formation. The authors state that the occluded oil is prevented from coming out during the first centrifuging by the restraining effect of the first 'Langmuir' film. The instrument has been used as a means of performing a 'mechanical fractionation' on castor oil, some part of which appears to have a different affinity for the metal from the rest.

Astronomical Topics

The Partial Lunar Eclipse of September 14.—Prof. C. D. Perrine, director of the Cordoba Observatory, sends a note on the final phase of this eclipse. He states that the departing shadow was dark greyish, almost black, and that it was considerably broader than the amount to be expected at the time, which was, however, not accurately noted. Its sharpness recalled a partial solar eclipse. He thinks that it was from fifty to a hundred miles broader than the computed value, and asks what the appearance was to those who saw the maximum phase of the eclipse. This was observed by the writer of this note, and there was an unmistakable sunlit rim at the moon's north limb; it was not measured, but agreed roughly with the predicted amount.

Prof. Perrine notes in his letter that there was still a considerable amount of volcanic ash in the air at the time; if the terrestrial region throwing the shadow had been in his neighbourhood, we might ascribe the broadening of the shadow to this cause; but actually it was far north of the equator, indeed near the arctic circle; the cause therefore is unexplained.

Star of Greatest Known Mass.—A few years ago Prof. J. S. Plaskett announced that the star B.D.+6° 1309, in Monoceros is a very massive spectroscopic binary, the minimum masses of the two components being 76 and 63 times that of the sun; this was the most massive star known, for Miss Maury showed that the mass of some 300 times the sun, announced by Ludendorff for Upsilon Sagittarii, was based on a misinterpretation of the shifts of lines in its spectrum; it is a massive star, but far below Ludendorff's estimate. Dr. J. A. Pearse announces (*Mon. Not. Roy. Astro. Soc.*, Oct.) the detection of another very massive star at Victoria Observatory; this is H.D. 698, magnitude 7, in Cassiopeia; its spectral type is *B9sek*; it is a binary with a period of 55·9 days, eccentricity 0·03; both spectra are visible, but that of the smaller star is faint; the minimum masses are 113·2 and 44·9 times that of the sun. An interesting feature is that for part of the revolution the *K* line of calcium appears triple, the third component being due to interstellar calcium. The strength of the latter line is used to deduce the distance of the star, which comes out as 1220 parsecs. The absolute magnitudes are −3·1 for the brighter star, and −1·6 for the fainter one, which is of type *B5*. The star gives further confirmation of the existence of interstellar calcium. It is only in very distant stars that the lines due to it can be detected, and only in certain spectral types; since if the star has broad calcium lines of its own, these mask the interstellar ones, unless they are separated by rapid motion in the line of sight.

Annual of the Astronomical Observatory of Madrid.—The annual of this Observatory, besides giving the usual information of an astronomical almanac, contains much other interesting matter. There is a table of the parallaxes, magnitudes and spectral types of the 36 newest stars, and another of the elements of comets seen at more than one apparition (there are two omissions, the comets Pons-Coggia-Winnecke-Forbes and Grigg-Skjellerup); there is also a definitive orbit of comet Wilk, 1930 II, by Rafael Carrasco:

$$\begin{array}{ll} T & 1930 \text{ Jan. } 22{\cdot}305227 \text{ U.T.} \\ \omega & \left.\begin{array}{l} 157^\circ\ 29'\ 18{\cdot}78'' \\ 179\quad 0\ \ 11{\cdot}78 \\ 124\ \ 31\quad 0{\cdot}23 \end{array}\right\} 1930{\cdot}0 \\ \Omega & \\ i & \\ \log q & 9{\cdot}8276021 \\ \log a & 2{\cdot}8975315 \\ \text{Period} & 22197 \text{ years.} \end{array}$$

He gave similar elements last year, but the present investigation is more exhaustive, including all known observations. Mr. F. E. Seagrave found a similar period, but he did not include so many observations.

Another useful chapter deals with the families of asteroids discovered by Prof. Hirayama, with diagrams showing how they are grouped. There is also a table of all the asteroids arranged in order of period, which for many purposes is more useful than the order of discovery. Finally, there are details of the observations of solar prominences made at Madrid in 1930.

Archæology of Central America*

IN default of any statement to the contrary, it is to be assumed that "Contributions to American Archæology" is to serve as a medium of publication for results of the activities of the Carnegie Institution of Washington in American archæological investigation which are not on a sufficiently large scale to justify a separate monograph. The magnitude of an excavation, fortunately, is no gauge of its importance, and although neither of the investigations in the field recorded here proved sensational in its results, each makes a contribution to the archæology of Central America of specific interest, if of limited range.

(1) The excavation of mounds at Baking Pot, British Honduras, by Mr. Oliver Ricketson afforded some interesting, if somewhat obscure, evidence bearing on burial customs under the Mayan 'Old Empire'. The mounds in question, situated about six miles from El Cayo, consist of two groups, lying in a clearing, and each surrounded by innumerable small house-mounds. Of these, Group II. was examined superficially only. Group I. consisted of three small plazas on which were a number of mounds or pyramids. A squarish domeshaped mound and a low platform mound on plaza 3 were the sites of the chief excavation. A fire-pit on plaza 2 was excavated to a depth of two metres by the removal of ashes and small flints showing the effects of intense heat. It was too deep for a cooking-pit and may have served as a crematorium.

On excavation, Mound G, the first of the two mounds on plaza 3, proved to be a burial mound, rectangular in outline with offsets on three sides. An unusual feature was the occurrence of several retaining walls of roughly worked stone on the slopes of the mound. If the top of the mound had once been reached by a stairway on the western slope, obviously the side of approach, it must have been of plaster and had vanished.

Fifteen burials were discovered in that part of the mound which was excavated. The last uncovered was apparently that of a person of importance, as it occupied a stone vault centrally situated in the mound and consisting of rough limestone blocks, the inner faces of which had been smoothed. They had been set in mortar and a cover was formed by limestone slabs, of which the edges had not been trimmed. The dimensions of the chamber, which was at a depth of two metres from the surface of the mound, were two metres in length by 45-50 cm. in width by 50 cm. in height. A narrow shelf of stone extending into the grave on both sides at the bottom reduced the width available for the disposal of the body to not more than 39-42 cm.; but its function was not evident. On the floor of the grave beyond the skeletal remains at head and foot were two black tripod pots.

The skeletal remains were badly preserved and offered little opportunity for examination. The body evidently had been laid on its face. With it were ear plugs and crude beads of jade, shell rosettes, fragments of worked bone, eleven small pieces of iron pyrites, and a number of small fragments of jade, round or in thin plaques.

The other skeletal remains found in the mound were in poor condition, and preservation of anything but fragments was in most cases impossible. Ten skulls were recovered in a condition which permitted of partial examination. Six show fronto-occipital deformation in varying extremes. Five are male, four indubitably female, and one probably female. The average cephalic index is 86·37, six ranging above this average to a maximum of 96·8.

The disposition of fourteen of the burials in the earth of the mound, some within, some without the retaining walls, is suggestive. Four are buried so near the surface and in such relation to one another as to suggest that they were sacrificial victims killed and hurled from the top of the mound and then buried as they lay.

Evidence for dating the site is lacking until the pottery has been more closely examined. Though not an important centre, it was evidently thickly populated at some time—it is suggested, on general grounds, not later than the transition between the Old Empire and the New, say the seventh to eighth century A.D.

(2) The study of the astronomical system of the Mayas has amply repaid the great amount of time and thought that has been spent upon it. The present work brings out the striking fact that the Mayas adopted the position value of numerals, with its necessary adjunct, a sign for zero, at least a thousand years before this step was taken in Europe. Their numerical system, which takes twenty as its base, is now thoroughly understood, and has brought to light the accurate knowledge that the Mayas attained with regard to the heavenly movements. Dr. Teeple gives 365·2420 days as the Maya determination of the length of the tropical year; this is about as accurate as the mean length of the Gregorian year, which is 365·2425 days; the truth lies midway between them; "but the Maya figure was reached a full thousand years before the Gregorian one".

In spite of this knowledge, the Maya appear to have used the 365-day year, letting the seasons drift round it; they also used a second reckoning by 260-day periods, called *tzolkins*; thus 73 *tzolkins* are exactly 52 of their years. No natural period coincides with the *tzolkin*, but it is very close to three-quarters of the eclipse-year, or interval between successive passages of the sun through the moon's ascending node. The Dresden Codex, the date of which is given as about A.D. 1100, is concluded to be an eclipse table. The mean length of the lunation was not so well determined as that of the tropical year. Two different values are mentioned, one being a day wrong in two centuries, the other a day in three centuries. Five Venus revolutions (synodic) were taken as equal to eight of their 365-day periods; this is right within a few hours.

Dr. Teeple has made great endeavours to correlate Maya dates with our calendar, but is at present not quite confident of the accuracy of the relation that he gives provisionally, though he has little doubt that the matter will eventually be settled. A hopeful point is that a total eclipse of the sun is calculated to have occurred on July 16, A.D. 790, on the site of a monument concluded to record an eclipse. The date agrees with Mr. Goodman's correlation.

(3) The excavation of the building since known as "the Temple of the Wall Panels" at Chichen Itzá, was undertaken as a part of the intensive campaign of excavation by the Carnegie Institution on that site. Its specific object was to further the investigation of the fusion of the Nahua and Mayan architectural systems which took place when, in the last 250 years before Chichen Itzá was abandoned in the middle of the fifteenth century, the city reached the height of its glory as a religious centre under alien overlords of

* Contributions to American Archæology, vol. 1, Nos. 1-4. No. 1: Excavations at Baking Pot, British Honduras, by Oliver Ricketson, Jr.; No. 2: Maya Astronomy, by Dr. John E. Teeple; No. 3: The Temple of the Wall Panels, Chichen Itzá, by Karl Ruppert; No. 4: Notes on the Metates of Chichen Itzá, Yucatan, by Gustav Strömsvik. (Publication No. 403.) Pp. iii+157+49 plates. (Washington, D.C.: Carnegie Institution, 1931.)

Mexican extraction. It was in this period that there was an outburst of architectural activity, in which the fundamental conception was Mayan, but the presence of an alien influence is to be seen in serpent columns, sloping lower walls, and other features.

The Temple of the Wall Panels was chosen for excavation on account of its central position in what is known as the Monjas group. This group would appear to have been the nucleus of the city, as it contains most of the pure Mayan buildings of Chichen Itzá, as well as structures that are doubtful and others that are certainly Nahua. The Temple of the Wall Panels was seen to be late from the presence of the drums of round columns on the mound; but beyond the fact that it was small, before excavation nothing was to be seen of its original plan or elevation. When finally cleared, it was found to face west and to consist of a solid pyramidal substructure surmounted by a temple, with a colonnade, forming an integral part of the building, lying directly to the west. The entire edifice rests on a terrace reached by two steps. The temple consisted of two chambers, each covered by a vaulted roof. Of the outer facing, little remains. In the debris of the talus on the northern and southern sides were discovered sculptured stones from panels and mask elements which had fallen from the outer walls. Two warriors are represented on the north panel, one having a long-nose head and an elaborate feathered headdress. The figures are the full height of the panels.

The entrance to the outer chamber is by a triple doorway, 6·71 metres wide, divided by two round columns. Each chamber has a crude shrine or altar. In the inner room a beautifully carved stone was discovered, the figures representing warriors.

In excavating the colonnade, of which the roof probably formed the approach to the temple, sculptured stones were found which had fallen face down. They were for the most part in sequence and have been fitted together. They proved to be elements of the panels of the exterior walls. They were not executed with that fineness of which the Chichen Itzá artists were capable, and it is evident that for detail and finish dependence was placed on the stucco, of which some still adheres to the stone. These panels are elaborately carved with numerous figures of men and animals.

Certain features justify the assignment of the temple to the Nahua period. These are the colonnade, serpent columns, roof *adornos*, a battered basal zone, sculptured panels depicting feathered serpents, the accoutrements of the warriors, and the sun-disk motive. The Atlantean figures which form part of the Nahua sculptural complex are here represented only in a column drum which had been re-used. This presupposes the building and razing of a structure of Nahua type before the erection of the Temple of the Wall Panels.

(4) The metate or milling stone upon which the peoples of aboriginal America grind their maize-corn was, and still is, among many of the Indian tribes the most important article of household equipment. Except for certain ceremonial examples from Central America, it is normally of simple and purely utilitarian form. This typological stability gives it a peculiar archæological significance, as it is little likely to be affected by fortuitous circumstance. It is therefore an admirable source of evidence for certain fundamental groupings. The metates of Chichen Itzá are considered by Dr. Strómsvik as falling into a classification of 'heavy grooved type', 'three-legged ungrooved large type', and 'three-legged ungrooved small type'. While suggesting the intrusion of an alien influence, he points to the necessity of more data on the distribution and cultural affinities of grooved and ungrooved metates in Mexico and Central America.

The A.I.V. Process of Conserving Green Fodder

IN these days of economic nationalism and of devalued currency in terms of gold, it is a cardinal principle to produce as much at home as natural conditions allow. Although only the Dr. Panglosses believe that Great Britain could feed her people entirely and adequately from her own resources, yet all who have studied the question think that we could go a long way towards this goal. Great Britain, for example, is one of the most favoured nations in regard to grass production, yet it imports many million pounds' worth each of butter, cheese, eggs, meat, and concentrated feeding stuffs which could be produced at home. The annual bill for imported concentrated foods is so high that efforts have been made recently to dry artificially the young, protein-rich grass and so conserve it for winter 'keep'. Up to date, experiments made with this object in view in Germany and Great Britain have failed to bring conviction to the economist, and it now looks as if the desired end is to be achieved by a modification of the old practice of ensiling. The ensiling of green fodder crops for use as winter keep has made great headway in New Zealand, the United States, Holland, and Germany, but the English farmer has been slow to realise its advantages. However, he has now an opportunity. Thanks to the enterprise of Imperial Chemical Industries, Ltd., a new chemical method of ensiling, which hails from Finland, has been launched in Great Britain, large-scale experiments having been undertaken at the company's research station at Jealott's Hill, Berks, and at various other places.

When ensilage is made in the ordinary way, in tower, stack, or pit, the green fodder undergoes various changes, due to enzymes and bacteria, which usually entail a loss of 15-30 per cent of its nutrients, and much more if anything goes wrong with the process. In the new Finnish process—called the A.I.V. process, after the initials of the discoverer, Prof. A. I. Virtanen —such changes are inhibited by maintaining the fodder at a hydrogen ion concentration of 3-4. This is achieved by spraying a dilute acid liquor on to the green crop as it is charged into a pit silo; and mould-growth is prevented by spraying the top layer with an anti-mould preparation, called 'Homesurma' (mould-death). The composition of the acid liquor is not revealed, but it is stated to consist mainly of hydrochloric acid, whilst 'Homesurma' is said to consist chiefly of allyl mustard oil. When the pit is fully charged, it must be sealed on the top as tightly as possible, for example, by means of sacking covered with clay or loam, as ingress of air is fatal to success. According to Prof. Virtanen, A.I.V. fodder contains a much higher content of digestible protein than ordinary silage; and he estimates the loss of nutrients in the preparation to be 0·2 per cent from respiration, nothing from decomposition of proteins, and 1·3 per cent from escaped juice.

The A.I.V. process has achieved remarkable success in Finland, where it has been taken up by the butter co-operative export society, Valio, which controls 90 per cent of the butter exported from that country. In 1927 and 1928, the process was being worked out

and tested mainly in the laboratory; in 1929, it was used on 3000 farms, and 30,000 metric tons of A.I.V. fodder was produced; in 1931, 100,000 tons was made on approximately 10,000 farms; and in 1932 the process is being used on 13,000 farms. All kinds of green crops have been ensiled, but legumes or young grass are best for feeding to milch cows.

The ordinary winter ration used in Finland for 800-gallon cows consists of concentrates, turnips, hay and straw: in the A.I.V. ration, all the turnips and much (in some cases all) of the concentrates are eliminated, together with much of the hay. Expenditure on imported concentrates has been reduced by 50-80 per cent, and at the same time the milk yield has increased. The animals readily eat the fodder, ensiled grass being preferred. The free acid is said to disappear before the fodder is fed, but on most of the Finnish farms using the process a small amount of chalk is included in the silage ration. It has been found that the animals do not tire of A.I.V. fodder, and that their general health remains excellent: the distribution of lime and phosphorus in the teeth and bones, and of lime, phosphorus, and chlorine in the muscles and blood, remains normal. The quality of the milk resembles that of summer milk, both the butter-fat and protein contents being slightly higher than when the cows are fed on the ordinary winter ration; and the butter made from winter milk lacks its usual brittleness owing to the oleic acid-content being maintained at summer level. Further, the high vitamin content is held to be of great importance to public health, as the majority of the inhabitants of northern countries rely mainly on milk and milk products for their supplies of vitamins A and D, and hitherto it has been found that the growth of children in Finland is practically confined to the months from July to December.

The only capital cost involved is that of making the silo pit, which has a diameter of 16½ ft. and a depth of 4 ft. 9 in. In Finland, where family labour is abundant and wood is cheap, this cost is very low. Unless the subsoil is chalk, the pit must be lined with wood, or with cement if there is danger of water seepage. A light wooden superstructure, which is transferable from pit to pit, must also be provided; it is placed over the pit when the green material reaches the ground level, and filling then proceeds until the superstructure is also full. The fresh material is then weighted, in a day or two it sinks to the ground level, and the superstructure is removed. Working costs vary with the crop ensiled, the yield per acre of the crop, and with the cost and efficiency of the labour. With labour, as in England, at about *8d.* per hour, the cost per ton of dry matter (about twenty per cent of the green weight) is estimated to be about *22s. 6d.*; if to this figure we add £2 per ton of dry matter as the inclusive cost of growing grass for ensilage with the aid of manures, we obtain a total of £3 *2s. 6d.* per ton, to which must be added a further small sum for cost of acid and depreciation of the silage pit.

Large-scale trials of the process are being made in Denmark as well as in Great Britain; in addition, the process has found a footing in Sweden and Norway; whilst in Germany, where some of Prof. Virtanen's claims are contested, the process, in its essential principles, has been officially adopted and is being widely advocated. If found to be a success in Great Britain, the adoption of the process will not only save the country millions of pounds per annum on imported concentrates, but will also provide what appears to be the only practical, economic solution of the problem of utilising flush growth of grass, which is one of outstanding importance in the management of grassland.

Buffalo-Fly in Northern Australia

FOR years past, serious complaints have come from cattle raisers in the northern areas of Australia about heavy economic losses due to irritation of stock by the buffalo-fly. This led the Commonwealth Council for Scientific and Industrial Research in 1930 to invite Prof. Eduard Handschin, of Basle, to undertake inquiries in Java and neighbouring islands, as well as on the mainland. The object was to examine possibilities of parasitic control of the pest. Prof. Handschin's full report is not yet available, but it is of interest at this stage to record some of the results of his eighteen months' work.

As with other alleged economic pests in Australia (flying fox, for example), careful inquiry has shown that *Lyperosia exigua* de Meijere, though serious in some places, is by no means responsible for all the damage hitherto attributed to it. This fly is present everywhere in the Dutch East Indies, where it is not regarded as a pest: its bad name in Australia is due in part to faulty observation. March and bush flies (*Tabanus* and *Biomyia* spp.) worry cattle more, in Handschin's opinion, than does *Lyperosia*. Loss of condition in travelling mobs is often put down to 'fly worry' when it is due rather to innutritious dry grass and water scarcity. Further, the quality of the stock in northern Australia is admittedly low. This undoubtedly increases the attractiveness, or susceptibility, of the cattle to the fly. Poor quality of stock is probably a cause rather than an effect of the abnormally heavy infestation that is frequently observed. In short, it is usual to attribute all fly damage to *Lyperosia* and to make it the scapegoat for every economic loss in northern Australia.

Nevertheless, it remains a distinct menace to cattle-raising, and its passage eastwards into the dairying herds of the coastal areas of Queensland might have serious results. Such spread is already occurring, but its geographic limits are set by conditions of temperature and humidity. The influence of these on time of development has been partially worked out by Handschin, who feels justified in maintaining that the buffalo-fly will never become established in the more southerly parts of Australia (western or eastern) and probably never farther south than Rockhampton in Queensland. There may be temporary incursions to lower latitudes, but they will not survive.

In the sparsely settled areas of the north, parasitism seems the only possible means of control. Nieschulz had already found a number of parasites in Java, mostly primary parasites of saprophagous *Muscidæ*, not confined to any species of these, but as easily bred on *Lyperosia* as on them. Twelve of them were reared in the laboratories of the Veterinary Research Institute at Buitenzorg, and *Spalangia sundaica* Graham (n. sp.), which was the must abundant in the field, offered the greatest promise as a possible control for *Lyperosia*. The female lives about 27 days and lays 160-170 eggs, each in a separate puparium of a fly.

There is a northern Australian species tentatively named *S. orientalis* Graham (n. sp.), morphologically quite distinct from *S. sundaica*, the female of which lives for 15 days and lays 75-85 eggs. In the hope of producing a more effective race, Handschin endeavoured to cross these two species. Males only were produced, indicating that fertilisation had not occurred. In the meantime, however, a special strain

of *S. sundaica* was reared for several generations on *Lyperosia* puparia only, and when the male of this was crossed with *S. orientalis* female, remarkable results were obtained, the female offspring living 32 days (instead of 15) and producing 250 eggs (instead of about 80). In other words, the time of life of the indigenous species was doubled and the fecundity trebled, both highly important characteristics in a fight against *Lyperosia*. The reverse cross gave females living only 10 days, instead of the 27 of the *S. sundaica* female, and producing 100 eggs instead of 180.

Five generations of the more promising cross were bred by Handschin, using all possible combinations of the parent and derived stock. The results are certainly striking, but further research is urgently necessary. Arrangements are in train for breeding the first cross and releasing it in selected areas near Darwin. If results justify it, the work will be extended in the wet season to the Gulf Country in North Queensland. The chances of appreciable success are, however, not great; hence no relaxation of quarantine restrictions can be permitted. An interim report on Handschin's observations, including descriptions of *S. sundaica* and *S. orientalis*, has been published.

Liquid Fuels

THE second jubilee memorial lecture to the Society of Chemical Industry, given by Dr. A. E. Dunstan, deals with the whole question of the utilisation of petroleum, oil from coal, synthetic oils, and related subjects, and is printed in *Chemistry and Industry* for October 7 and 14. Natural gas is also dealt with.

Dr. Dunstan pointed out in what directions the industrial processes are undergoing modification. In the case of motor spirit, the tendency to gum formation, which is always present to some extent, is minimised by the addition of inhibitors such as di- and tri-hydric phenols and some aromatic amines and derivatives. Tendency to freezing in the case of spirit for use in military aviation is overcome by blending with methyl and ethyl alcohols, the hygroscopic properties of which may be restrained to some extent by the addition of benzene, amyl and butyl alcohols and phenol as binders.

A limit appears to have been reached in the increase of compression ratio possible without detonation even when special fuels are used, and research into the effects of other factors in engine design is suggested. The relation between chemical composition (paraffinic, naphthene, aromatic) and tendency to detonation in a fuel is not absolute, and anti-knock valuation can be made only by engine tests. The restriction on the use of cracked spirit for aviation may be removed if the authorities can be satisfied as to its keeping properties. Compression ignition (Diesel type) is steadily advancing in importance as compared with spark ignition, particularly for heavy transport, and Dr. Dunstan pointed out its advantages. Even if the price of fuel were equal to that of petrol, there would still be a very substantial margin of benefit from compression ignition. The bearing of this on the liquid fuel industry was made clear.

The production of oil from coal was carefully discussed and the conclusion reached that it appears to represent strategic rather than economic advantages. If the total coal used for power, heating, etc., as well as hydrogenation is taken into account, the most successful processes of hydrogenation will at present make only 1 ton of oil from 4 tons of coal, and the plant is not only extremely complicated but also exceedingly costly. Although hydrogenation appears to be the most hopeful line technically for the production of liquid fuels, its application to coal or even tar cannot be put forward at the present stage as a business proposition.

University and Educational Intelligence

BIRMINGHAM.—The Huxley lecture is to be delivered by Sir Arthur Salter in the Medical Theatre of the University, Edmund Street, on December 1 at 5.30. The subject of the lecture is: "Next Steps in World Recovery".

CAMBRIDGE.—Sir Charles Sherrington, Waynflete professor of physiology in the University of Oxford, has been appointed Rede lecturer for the year 1933.

W. G. Walter, of King's College, has been elected to the Michael Foster research studentship in physiology.

Dr. E. T. S. Walton, of Trinity College, has been awarded the Clerk Maxwell scholarship.

The Adam Smith prize has been divided between K. S. Isles, of Gonville and Caius College, and J. H. Kirk, of King's College.

Dr. N. J. T. M. Needham, of Gonville and Caius College, has been approved for the Sc.D. degree.

The Governing Body of Emmanuel College invites applications for a research studentship which will be awarded in July 1933. The award will be made on evidence submitted by the candidates which should include (1) a birth certificate, (2) two certificates of good character, (3) a statement of the proposed course of research, (4) evidence of general ability and of special fitness for the proposed course of research, supported by letters from two professors and other teachers, (5) a statement of emoluments or awards, already granted, or likely to be granted, from other bodies or persons and tenable at Cambridge. Applications must be sent to the Master in time to reach him not later than June 30. Preference will be given to candidates who have already completed one but not more than two years of research. The studentship has a maximum annual value of £150 and is awarded and normally held for two years but may be renewed for a third year. The studentship is not tenable by a woman or by a graduate of the University of Cambridge.

LONDON.—The University Court has gratefully accepted an offer received from Mr. William Page to give to the University, subject to certain conditions, the copyright and material of the Victoria County History.

THE building extension of the Northampton Polytechnic Institute, St. John Street, E.C.1, will be officially opened by H.R.H. Prince George on December 2, at 7 P.M.

THE twentieth election to Beit fellowships for scientific research will take place on or about July 14, 1933. Not more than three fellowships will be awarded on this occasion. Candidates must be graduates of a university of the British Empire and under twenty-five years of age. The annual value of a fellowship is £250 and it is tenable at the Imperial College of Science and Technology. Further information can be obtained from the Rector, Imperial College, South Kensington, London, S.W.7.

Calendar of Geographical Exploration

Nov. 21, 1793.—Japan and Russia

A storm drove a Japanese vessel carrying rice to Yezo far out to sea, and in early June of the following year the Japanese sailors reached the Aleutian Islands, recently taken by the Russians. They remained there some ten months and reached Okhotsk at the end of June of the next year. Thence they were taken overland to Irkutsk, where they remained eight years. They were then taken to St. Petersburg, where the Czar received them and gave them furs. Finally they were sent back by sea round Cape Horn to Japan with Capt. Krusenstern's expedition, which was intended to conduct a Russian envoy to Japan. They were handed to the Japanese authorities in 1805. A Japanese work written in 1830, in four volumes, describes their experiences. It is also interesting to note that Krusenstern's voyage was the first Russian circumnavigation of the globe. He left Kronstadt in 1803, rounded Cape Horn, made some observations in the Marquesas Islands and thence proceeded to Kamchatka and Japan; he examined the strait between Sakhalin and the mainland but thought that Sakhalin was a peninsula of Asia. Lisianski, who accompanied Krusenstern in another vessel, discovered the island named after him. The Russian voyage added much to the scientific knowledge of the Pacific; observations of temperature in deep waters and of currents and tides were taken and astronomical records were kept.

Nov. 21, 1754.—Basin of the Saskatchewan

Anthony Hendry, on an expedition for the Hudson Bay Company, reached his farthest west, about 114° W., a little south of 52° N. Hendry left York Factory at the mouth of the Hayes River in June 1754, and using various portages reached Moose Lake and the Saskatchewan River. He explored the region between the north and south branches of that river, spent the winter with the Blackfeet Indians and returned via the Red Deer River to the South Saskatchewan.

Nov. 23, 1878.—British Honduras

Henry Fowler, the Colonial Secretary, started from Belize, went up the Belize River and explored much of the previously unknown interior. Capt. T. A. Joyce, of the British Museum, has carried out important archæological work in this region in recent years, disclosing a great wealth of Maya ruins. These surveys have also contributed to geographical knowledge of a little-known region.

Nov. 25, 1913.—Gertrude Bell in Arabia

Gertrude M. L. Bell arrived at Damascus, whence she set out on her 1500 mile journey in Arabia. She travelled to Hasan near Teima and thence turned east, reaching Hayil, which had only once previously seen a European woman, Lady Anne Blunt, who had visited it in 1878. The cool reception which she received here made it impossible for her to go south as she had hoped and she turned north-east to the Euphrates, returning to Damascus via Bagdad and Palmyra. Her Arabian experiences began in 1899; her subsequent travels and archæological explorations made her reputation as an authority on Asia Minor and the northern borderlands of Arabia. She died in Bagdad in 1926 while engaged in the organisation of a museum of antiquities.

Societies and Academies

LONDON

Royal Society, Nov. 10.—Lord Rutherford, C. E. Wynn-Williams, W. B. Lewis and B. V. Bowden: Analysis of α-rays by an annular magnetic field. With the assistance of Dr. J. Cockroft, an electromagnet has been designed which provides a uniform magnetic field, of the order of 10,000 gauss, in an annular gap in which α-rays can be bent into a circle of 40 cm. radius. The particles are emitted from a source placed in the gap, and are detected by a small ionisation chamber symmetrically situated on the opposite end of a diameter. The interior of the whole magnet is exhausted to a low pressure (0·001 mm. mercury). As in previous experiments the ionisation chamber is connected to an amplifier, and individual α-particles are automatically counted by a system of thyratrons. The analysis is carried out by adjusting the magnetic field so as to bring groups of different velocities successively on to the slit of the counting chamber, the high velocity edge of a group being very sharply defined. Moreover, it is necessary to measure small changes of the magnetic field with great accuracy. A special method has been developed for this purpose, and the relative velocities of a number of α-particle groups have already been determined with an accuracy of about 1 in 3,000. The weak group of α-particles from radium C, numbering only 1 in 4,000 of the main radium C′ group, comprises two distinct components.—**W. A. Bone, D. M. Newitt and D. T. A. Townend**: Gaseous combustion at high pressures (14). Explosions of hydrogen–air and carbonic oxide–air mixtures at initial pressures up to 1,000 atmospheres. With regard to the actual explosions it was found that:—(1) In those of theoretical hydrogen–air media there was a quite definite increase in the explosion times with density at initial pressures exceeding 250 atmospheres; although at 750 atmospheres detonation was instantaneously set up at the firing point with such violence as to preclude work at any higher pressures; (2) in explosions of theoretical carbon monoxide–air media the characteristic lag in the explosion time, as well as the exothermic effects observed during the cooling period—both of which had hitherto consistently increased with the density—reached their maxima at an initial pressure somewhere between 350 and 500 atmospheres, and thereafter remained constant up to 1,000 atmospheres, indicating that the nitrogen activation effect had reached maximum within this density range; (3) in $2CO + O_2 + 3{\cdot}76CO$ explosions the explosion times, which were always very much shorter than in the corresponding $2CO + O_2 + 3{\cdot}76N_2$ explosions and had remained nearly constant up to initial pressures of 250 atmospheres, began definitely to increase thereafter with the density, and about the same point some slight carbon deposition began to be manifest during the explosions, the two circumstances probably being connected. The rates of pressure fall during the first second of the cooling period immediately after the attainment of maximum pressure were always much faster than in the corresponding $2CO + O_2 + 3{\cdot}76N_2$ experiments.

Society of Public Analysts, Nov. 2.—Theodore Rendle: Observations on changes in raspberries after picking. The ripening process in raspberries is more rapid than in most fruits. Accompanying the ripening

there occurs the production of a relatively large amount of volatile organic bodies not due to the action of micro-organisms. The pectic substances in raspberries are subject to rapid change, with the destruction of their gelling power; this change is arrested by the application of heat.—**W. R. Schoeller** and **H. W. Webb**: The separation of uranium from tantalum, niobium and titanium. Uranium is quantitatively precipitated by tannin from neutralised tartrate solution in presence of ammonium acetate and chloride. It is quantitatively precipitated from oxalate solution by tannin and a slight excess of ammonia. Uranium, like zirconium, thorium, aluminium and iron (group *B*) can be quantitatively separated from tantalum, niobium and titanium (group *A*) by tannin precipitation of the last three elements from feebly acid oxalate solution half-saturated with ammonium chloride. In tartaric hydrolysis, uranium interferes with the normal course of precipitation in the case of niobium, but not of tantalum or of mixed pentoxides in which tantalic oxide preponderates.—**E. J. King**: A new form of filter stick: its use in gravimetric analysis. A new form of filter stick, particularly suitable for the micro-analysis of silicic acid, has been devised.—**F. J. Warth**: A new method for the iodimetric titration of phenols. The conditions under which iodine is absorbed by phenols are discussed. Under certain specified conditions, in the presence of sodium hydroxide two-thirds of the theoretical amounts of iodine are absorbed by phenols, including the cresols.

PARIS

Academy of Sciences, Oct. 10 (195, 589-632).—**Maurice Fréchet**: The behaviour of certain nuclei of Fredholm repeated indefinitely and the probabilities in chain.—**J. Mirguet**: A class of surfaces admitting a continuous tangent plane.—**A. Kulakoff**: The relations between the real parts of the characters of groups.—**Pierre Dive**: The identity of two bodies possessing the same Newtonian potential in a common interior region.—**J. Pérès** and **L. Malavard**: The application of the electrical method to a problem concerning the wing of finite spread.—**Li Hen**: Some statistical properties of the Cepheids.—**P. de Fonbrune**: A new micro-manipulator. A pneumatic control is described possessing the advantages that the needle or micro-pipette is unaffected by shaking of the hand; all movements of the control lever are exactly reproduced on the microscopic scale by the needle point. More than one of these instruments can be used in the field of the objective at the same time.—**A. Piccard** and **M. Cosyns**: The study of the cosmic radiation at great altitudes. Results obtained during the ascent made on August 18, 1932. A curve is given showing the relation between the barometric pressure and the intensity of the radiation, the latter measured by two types of ionisation chamber. As regards the effects of screens, 4 cm. of paraffin had no visible effect, but 4–5 cm. of lead caused a diminution of 20–35 per cent.—**Mlle. Suzanne Veil**: The periodic precipitation of some silver salts. Study of the precipitation of silver arsenate, chromate and phosphate in gelatine.—**Kapp**: The determination of hydrogen sulphide in trade effluents. The errors caused by the oxidation of the gas by the oxygen dissolved in the effluent can be avoided by adding cadmium sulphate: cadmium sulphide is not readily oxidised and can be carried to the laboratory for analysis without change.—**A. Stieber**: Two combinations of boron trichloride, one with hydrogen arsenide and the other with phosphorus trichloride. These new compounds have the formulæ $BCl_3.AsH_3$ and $BCl_3.PCl_3$.—**G. Schuster**: The use of hydrobromic acid for the characterisation of the arylarsinic acids.—**G. Florence, J. Enselme** and **M. Pozzi**: Contribution to the study of the variations as a function of the *p*H of the ultra-violet spectra of some hexavalent heterocyclic compounds.—**J. Durand**: The granite of Laguépie (Tarn-et-Garonne).—**J. Malavoy** and **S. Serpokryloff**: New geological observations in the loop of the Niger.—**F. Link**: Records of atmospherics. The observations were made at the Observatory of the Pic-du-Midi at an altitude of 2,860 metres, between November 1931 and August 1932. A statistical study of the results gave maxima corresponding to heights of 35 km. 115 km. and 235 km. The first maximum corresponds with the maximum ozone concentration, the second with the Kennelly-Heaviside layer and the third to the reflecting layer found by the echo method.—**Paul Chauchard**: The variations of salinity measured by means of the electrical conductivity: study of the Rance at Le Chatelier.—**N. Em. Renescu** and **B. B. Olszewski**: Chloral hydrate in the organism. The narcotic action of chloral hydrate has been variously attributed to chloroform produced by decomposition, to the formation of carbon monoxide, and to the effects of unchanged chloral hydrate. The author's experiments are in agreement with the last view. Chloral was found in relatively large quantities in all the organs, whilst chloroform was found in traces only and was absent from some organs.—**J. R. Denis, P. Paris** and **P. Rémy**: New experiments, under natural conditions, on the phototropism of fresh-water plankton.—**Emile André** and **Armand Bloch**: The etho-esters of glycerol or etho-glycerides of the liver oil of *Scymnorhinus lichia*.—**M. Aynaud**: The parasitism of Infusoria in the walls of the stomach of the sheep.—**A. Lacassagne**: The appearance of cancer of the breast in male mice, submitted to injections of folliculin.

Forthcoming Events

MONDAY, Nov. 21

ROYAL SOCIETY OF ARTS, at 8—(Fothergill Lecture).—Com. A. N. G. Firebrace: "Fire Fighting".

CHADWICK PUBLIC LECTURE, at 7.30—(at the Technical College, Bradford).—Prof. S. D. Adshead: "Some Recent Developments in the Housing Problem".

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Evelyn Cheesman: "The Island of Malekula, New Hebrides".

TUESDAY, Nov. 22

BRITISH SCIENCE GUILD, at 4.30—(Eighth Annual Norman Lockyer Lecture, in the Goldsmiths' Hall, Foster Lane, E.C.).—Sir Frank Smith: "Industrial Research and the Nation's Balance Sheet".

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30—(at the School of Hygiene and Tropical Medicine, Keppel Street, W.C.1).—Gabrielle M. Vassal: "Life in the French Congo".

KING'S COLLEGE, LONDON, at 5.30.—M. T. Halcrow: "The Water Power Developments of the British Isles" (succeeding lectures on Nov. 29 and Dec. 6).

UNIVERSITY OF LEEDS, at 8.—Dr. C. D. Ellis: "Recent Advances in our Knowledge of the Atom".

WEDNESDAY, Nov. 23

ROYAL ANTHROPOLOGICAL INSTITUTE, at 5—(at the School of Hygiene and Tropical Medicine, Keppel Street, W.C.1).—Discussion on "The Evidence of Man's Kinship with the Primates", to be opened by Dr. Solly Zuckerman.

FRIDAY, Nov. 25

Chadwick Public Lecture, at 7.30—(at the Town Hall, Gateshead).—Dame Louise McIlroy: "Maternal and Infant Welfare".

Chemical Society, at 5.30—(Fourth Liversidge Lecture, in the Chemistry Lecture Theatre, University of Birmingham).—Dr. F. W. Aston: "Physical Atomic Weights".

University College, London, at 5.30.—Sir James Frazer: "The Fear of the Dead in Primitive Religion" (succeeding lectures on Nov. 29 and Dec. 1).

Royal Institution, at 9.—Dr. H. Knox-Shaw: "Observational Evidence for the Expansion of the Universe".

SATURDAY, Nov. 26

University of Cambridge, at 5—(Henry Sidgwick Memorial Lecture in the College Hall, Newnham College).—Sir James Jeans: "The Farthest Depths of Space".

Official Publications Received

GREAT BRITAIN AND IRELAND

Birmingham Bureau of Research on Russian Economic Conditions. Memorandum No. 7: i. Foreign Trade; ii. Monetary Conditions; iii. Indices of Wholesale Prices; iv. State Budget. Pp. 24. (Birmingham: The University.)

Medical Research Council. Special Report Series No. 174: Medical Uses of Radium; Summary of Reports from Research Centres for 1931. Pp. 59+4 plates. (London: H.M. Stationery Office.) 1*s*. 3*d*. net.

Journal of the Chemical Society. October. Pp. iv+2505-2667+viii. (London: Chemical Society.)

University of Reading: The National Institute for Research in Dairying. Annual Report for the Year ending 31st July, 1931. Pp. 90. (Reading.)

Proceedings of the Royal Society of Edinburgh, Session 1931-1932. Vol. 52, Part 3, No. 21: Relative Co-ordinates. By A. G. Walker. Pp. 345-353. 9*d*. Nos. 22 and 23: Tables of the Elliptic-cylinder Functions and Zeros and Turning Points of the Elliptic-cylinder Functions. By Dr. E. L. Ince. Pp. 355-433. 7*s*. No. 24: Adrenaline and the Œstrous Cycle in the Mouse. By Dr. J. M. Robson. Pp. 434-444. 1*s*. (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.)

Transactions of the Institute of Marine Engineers, Incorporated. Session 1932. Vol. 44, No. 9, October. Pp. 427-474+xxxiv. (London.)

Air Ministry: Aeronautical Research Committee: Reports and Memoranda. No. 1472 (T.3246): Measurement of Position Error on High Speed Aircraft. By R. K. Cushing. Pp. 5+5 plates. 6*d*. net. No. 1487 (S.91): Effect of Float Setting on Take-off and Top Speed of the IIIF. By J. L. Hutchinson. Pp. 2+1 plate. 3*d*. net. (London: H.M. Stationery Office.)

A Mosquito Summary. By John F. Marshall. Pp. 8. (Hayling Island: British Mosquito Control Institute.) 9*d*.

A Report on the Museums of Canada, by Sir Henry A. Miers and S. F. Markham, to the Carnegie Corporation of New York, to which is appended a Directory of the Museums of Canada and other parts of the British Empire on the American Continent. Pp. vi+63+2 plates. Directory of Museums and Art Galleries in Canada, Newfoundland, Bermuda, the British West Indies, British Guiana and the Falkland Islands. Compiled by Sir Henry A. Miers and S. F. Markham. Pp. 92. 5*s*., with Report. (London: The Museums Association.)

OTHER COUNTRIES

The Imperial Council of Agricultural Research. Scientific Monograph No. 3: The Open Pan System of White Sugar Manufacture. By R. C. Srivastava. Pp. vi+141+7 plates (Calcutta: Government of India Central Publication Branch.). 3.2 rupees; 5*s*. 6*d*.

Education, India. Education in India in 1929-30. Pp. iv+76. (Calcutta: Government of India Central Publication Branch.) 1.4 rupees; 2*s*.

Report of the Botanical Survey of India for 1930-31. Pp. 12. (Calcutta.)

Survey of India. Geodetic Report, Vol. 7, from 1st October 1930 to 30th September 1931. Pp. xvii+150+29 plates. (Dehra Dun.) 3 rupees; 5*s*. 3*d*.

State of Illinois: Department of Registration and Education: Division of Natural History. Bulletin, Vol. 20, Article 1: Initial Studies of American Elm Diseases in Illinois. By Hubert A. Harris. Pp. iii+70. (Urbana, Ill.)

Indian Central Cotton Committee: Technological Laboratory. Technological Bulletin, Series B, No. 14: Variations in the Properties of the Cotton Fibre in relation to its Position on the Surface of the Seed. Part 1: Fibre-Length; Part 2: Fibre-Weight; Part 3: Fibre-Strength. By Ram Saran Koshal and Dr. Nazir Ahmad. Pp. ii+56. (Bombay.) 1 rupee.

L'Influence solaire et les progrès de la météorologie: résultats de 50 années d'observations solaires et météorologiques comprenant les observations et les recherches effectuées à Talence à partir de 1900. Par Henri Mémery. Pp. iv+23. (Talence: Observatoire de Physique solaire et de Météorologie.)

U.S. Department of Commerce: Bureau of Standards. Bureau of Standards Journal of Research. Vol. 9, No. 4, October, Research Papers Nos. 482-492. Pp. 457-582. (Washington, D.C.: Government Printing Office.) 25 cents.

Proceedings of the American Philosophical Society. Vol. 71 No. 6. Pp. 309-410. (Philadelphia.)

Veröffentlichungen aus dem Kaiser Wilhelm-Institut für Silikatforschung in Berlin-Dahlem. Herausgegeben von Prof. Dr. Wilhelm Eitel. Band 5. Pp. iv+212. (Braunschweig: Friedr. Vieweg und Sohn A.-G.) 28 gold marks.

Annals of the Observatory of Lund. No. 3: Lund Observatory Tables for the Conversion of Equatorial Co-ordinates into Galactic Co-ordinates based on the Galactic Pole R.A. $12^h\ 40^m$; Dec. $+28°$ (1900.0). Computed under the direction of and provided with an Introduction by John Ohlsson. Pp. xxiii+147. (Lund.)

Meddelande från Lunds Astronomiska Observatorium. Ser. 2, Nr. 65: Second List of Stars with Large Proper-Motions in the Ag-Zone of Lund. By W. Gyllenberg. Pp. 19. 1.50 kr. Ser. 2, Nr. 66: Positions of 241 Stars, mainly Long-period and Irregular Variables, and Proper Motions for 117 of these Stars. By Frida Palmér. Pp. 63. 5.50 kr. (Lund.)

Tätigkeitsbericht der Sternwarte Lund für das Berichtsjahr 1931. Von Knut Lundmark. Pp. 11. (Lund.)

Commonwealth of Australia: Council for Scientific and Industrial Research. Bulletin No. 66: The Influence of Growth Stage and Frequency of Cutting on the Yield and Composition of a Perennial Grass, *Phalaris tuberosa*. By Dr. A. E. V. Richardson, H. E. Trumble and R. E. Shapter. Pp. 35. Pamphlet No. 32: The Chemistry of Australian Timbers. Part 2: The Chemical Composition of the Woods of the Ironbark Group. By W. E. Cohen, A. L. Baldock and A. G. Charles. Pp. 36. (Melbourne: H. J. Green.)

Indian Journal of Physics, Vol. 7, Part 4, and Proceedings of the Indian Association for the Cultivation of Science, Vol. 16, Part 4. Conducted by Sir C. V. Raman. Pp. 285-351. (Calcutta.) 1.8 rupees; 2*s*.

Paleontologiese Navorsing van die Nasionale Museum, Bloemfontein. Deel 2, Stuk 3: Die Stamlyn van die Sebras. Deur Dr. Ir. E. C. N. Van Hoepen. Pp. 23-37. (Bloemfontein.)

Annale van die (Annals of the) Transvaal Museum. Vol. 15, Part 1, 1st October. Pp. 122. (Pretoria: Government Printer.)

Scientific Papers of the Institute of Physical and Chemical Research. No. 383: On the Singlet Principal Series of Mercury. By Yoshio Ishida and Shigeru Hiyama. Pp. 79-82+plates 13-15. 15 sen. Nos. 384-392: The Effect of Humidity on Supersonic Velocity in Air, by Masao Kinoshita and Chihiro Ishii; The Most Probable Values of e, e/m and h, by Kamekichi Shiba; Carotin in Mango Fruit (*Mangifera indica* Lin.), by Ryo Yamamoto, Yasuyosi Osima and Teruo Goma; On the Carotinoids in Fresh Tea-Leaf and Fermented Tea, by Ryo Yamamoto and Tosiro Muraoka; On the Organic Acids in the Fruits of Ceylon Olive (*Elæocarpus serratus* Lin.), by Ryo Yamamoto, Yasuyosi Osima and Teruo Goma; On the Red Colouring Matter of *Hibiscus babdariffa* L. (a new Glycoside Hibiscin), by Ryo Yamamoto and Yasuyosi Osima; The Carotin in the Fruit of *Areca catechu* Lin., by Ryo Yamamoto and Tosiro Muraoka; On the Size of Fog Droplets, by Masao Kinoshita and Kiyoshi Uchiyama; The Effect of Superimposed Alternating Magnetic Fields upon Dielectric Loss-Angles, by Yoshitaro Fujikawa and Jiro Kitasato. Pp. 83-162. 60 sen. (Tokyo: Iwanami Shoten.)

U.S. Department of the Interior: Office of Education. Bulletin, 1931, No. 20: Biennial Survey of Education in the United States, 1928-1930. Chapter 1: Statistical Summary of Education, 1929-30. By Emery M. Foster. Pp. 12. (Washington, D.C.: Government Printing Office.) 5 cents.

Palæontologia Sinica. Series C, Vol. 7, Fascicle 3: On the Fossil Vertebrate Remains from Localities 2, 7 and 8 at Choukoutien. By C. C. Young. Pp. iv+24+1 plate. (Peiping: Geological Survey of China.)

Field Museum of Natural History. Zoological Series, Vol. 18, No. 11: Birds of Western China obtained by the Kelley-Roosevelts Expedition. By Outram Bangs. (Publication 314.) Pp. 341-379. (Chicago.) 25 cents.

Proceedings of the United States National Museum. Vol. 81, Art. 13: The Trematode Parasites of Marine Mammals. By Emmett W. Price. (No. 2936.) Pp. 68+12 plates. (Washington, D.C.: Government Printing Office.)

Ceylon. Part 4: Education, Science and Art (D). Administration Report of the Director of Agriculture for 1931. By Dr. W. Youngman. Pp. D163. (Colombo: Government Record Office.) 1.65 rupees.

Report of the Aeronautical Research Institute, Tôkyô Imperial University. No. 85: Thomson Effect of Crystalline Substances. By Yositosi Endô. Pp. 115-149. 0.40 yen. No. 86: On the Balancing of Two-stroke 12-Cylinder Engines. By Fujio Nakanishi. Pp. 151-159. 0.15 yen. No. 87: A New High-Speed Indicator for Internal Combustion Engines. By Fujio Nakanishi, Masaharu Itô and Kikuo Kitamura. Pp. 161-177. 0.25 yen. (Tôkyô: Koseikai Publishing House.)

Journal of the Faculty of Science, Imperial University of Tokyo. Section 2: Geology, Mineralogy, Geography, Seismology. Vol. 3, Part 5: The Seven Islands of Izu Province, a Volcanic Chain. By Dr. Bundjiro Kotô. Pp. 205-219+4 plates. 0.70 yen. Vol. 3, Part 6: Tertiary Mollusca from the Coalfield of Uryu, Ishikari. By Matajiro Yokoyama. Pp. 221-247+4 plates. 0.70 yen. Section 3: Botany. Vol. 2, Part 6: Morphological Studies of *Anemonopsis*, *Actæa* and *Cimicifuga*. By Masao Kumazawa. Pp. 413-454. 0.70 yen. Vol. 2, Part 7: On the Structure and Affinities of some Cretaceous Plants from Hokkaido, Second Contribution. By Yudsuru Ogwa. Pp. 455-483+plates 22-24. 0.70 yen. Vol. 4, Part 1: On the Systematic Importance of Spodograms in the Leaves of the Japanese Bambusaceae. By Kiichi Ohki. Pp. 130. 1.70 yen. (Tokyo: Maruzen Co., Ltd.)

Memoirs of the College of Science, Kyoto Imperial University. Series B, Vol. 8, No. 1. Pp. 80. (Tokyo and Kyoto: Maruzen Co., Ltd.)

Government of India: Meteorological Department. Magnetic, Meteorological and Seismographic Observations made at the Government Observatories, Bombay and Alibag, in the Year 1929 under the direction of Dr. S. K. Banerji. Pp. iv+138+5 plates. (Calcutta: Government of India Central Publication Branch.) 12.2 rupees; 19*s*. 6*d*.

Tanganyika Territory: Geological Survey. Annual Report, 1931. By Dr. E. O. Teale. Pp. ii+51. (Dodoma.) 2*s*. 6*d*.

The Scientific Outlook

It might have been expected that two such addresses as those delivered by Sir Alfred Ewing and Prof. Miles Walker at the York meeting of the British Association would have provoked a storm of criticism. Much of the criticism has, however, been directed at the details of the scheme proposed by Prof. Miles Walker, and some of the critics have assumed that his address advocated the participation in government of the engineer as distinct from other scientific workers, or indeed from those possessing a scientific outlook or the capacity to assess technical and scientific factors. Few of the critics have revealed any appreciation of the difficulties with which mass production confronts our civilisation or the moral weakness of man as compared with his tremendous command over natural forces.

The fact that both addresses were delivered by engineers has made it easier for prejudice to obscure the real issues by representing the addresses as sectarian clamourings for greater power. The fundamental challenge which they issue to the present order was ignored and it was left for Prof. J. L. Myres, at the Oxford meeting of the Association of Special Libraries and Information Bureaux, in an address on "Science and the Humanities", to direct attention to this challenge. Prof. Miles Walker's address does not so much outline an experiment in sociology, an attempt to relate knowledge and power more effectively and to eliminate prejudice, as offer a challenge to the general outlook of to-day, the poverty of which is one of our most serious troubles. Men have assumed too easily that the present depression will be ended by the old methods and that a return to prosperity will come without special effort.

Two things are involved in any such effort, on both of which Prof. Miles Walker touches: accurate knowledge of the changes which are taking place in our civilisation as a result of the application of scientific discoveries, and particularly of the consequences of power production and of the increased means of communication, whether in the sense of transport or of intelligence such as in broadcasting; and secondly, the training which must now be given to people in this age to render them competent to live.

It is at this point that we reach the essential challenge to modern politics, economics and education implicit in the last part of Sir Alfred Ewing's address. What society must inevitably

consider is the relative value of science and the humanities both in the organisation and development of the world order and in the preparation of the individual members to enjoy the privileges and discharge the responsibilities inherent in membership of a society based on scientific achievements. The criticism of the scientific training given by our existing educational system, which came from Prof. Miles Walker, is supported by similar criticism from many other quarters; in neither education, politics nor economics is it wise to assume that our present institutions will stand the test without radical transformation.

The relative contribution of science and the humanities at this juncture of national or world affairs cannot be determined merely by reference to discussions on this subject in the past. The question must be examined in relation to the factors of to-day, and Prof. Myres in his analysis wisely refers us back to the main purposes of any system of education. One main object of education must be to place at the disposal of the next generation the experience accumulated in the past of what takes place around us and of the way in which people react to their environment, leaving it to the coming generation to make what use it chooses of such experience and to develop its own interpretation. This is, of course, the attitude which in the past scientific workers have adopted towards their own discoveries. They have been content for others to make of them what use they would and have been comparatively indifferent to the far-reaching consequences which for good or ill have sometimes flowed from their application. It is this indifference, or the divorce of knowledge from life, that has marred much of our teaching of science and created a prejudice against learning.

The economic consequences of the increased productive powers conferred by mechanical science, the prostitution of scientific knowledge to destructive purposes in armaments, the misuse or abuse of the advantages of modern transport, radio, the cinema for anti-social purposes, and the immense powers for mischief which the application of modern scientific discoveries puts in the hands of careless or vicious individuals in themselves have brought many to realise that neither science nor society can continue to be unconcerned with the social and moral consequences of scientific research. It is, however, less frequently perceived that brilliant progress in scientific research and discovery can proceed side by side with the full development of moral qualities and æsthetic or artistic tastes, and that in fact in the absence of such an environment scientific advance is impeded.

The pursuit of this main objective in education accordingly leads us to realise how closely related are scientific achievement and cultural or moral standards. Prof. Myres pointed out, however, how much more closely they are related in the second main objective of education, the training of the growing generation in the use of knowledge. This involves the development of human qualities and individualism, the teaching of self-consciousness and of control of oneself, individually and in relation to others. This aspect of knowledge or information is often overlooked, and results in the rigid distinction between the natural sciences and the humanities which has worked so much mischief in education. The human sciences—human biology, psychology, and statistical economics—form a coherent system and are a fitting subject of scientific study, while moral, political, economic and æsthetic subjects have a geographical as well as a historical aspect or distribution. It is only when the geographical distribution is taken into account that the humanities come into a right relation with life. Individuals and societies alike have a geography and a historical geography as well as a biography, and this inevitably wears thin the distinction between science and the humanities.

Moreover, the distinction between pure and applied science rests on essentially the same factors. So long as they are concerned with problems which have a systematic solution independent of local or temporary conditions, even agriculture and engineering are in effect pure sciences. It is only when they are taking account of local or temporal factors that they become 'applied', and perhaps one reason why so much is at present expected from the engineer is that the liberal traditions of the engineering profession make full allowance for distribution considerations. Accordingly, it should be obvious that a systematic science can only be one factor in education for life. It stands apart from the central mass of knowledge and needs supplementing. Similarly a so-called human science has little value when it becomes systematised and ceases to reveal something significant about man.

We may humanise the teaching of a systematic science by devoting more attention to its historical growth and regional applications, as is seen in the growing use of anthropology in the administration

and education of the backward races. We may clarify and intensify the teaching of the humanities by a firmer distinction between their systematic aspect and those historical and regional reconstructions which alone can set the present civilisation in an intelligible perspective. In so doing we should undoubtedly increase the effectiveness of the training we give as a preparation for life, but such teaching and training demand *a priori* an adequate vision on the part of those giving it. They must themselves have put their minds accurately and intelligently on the facts and situations they have to face.

It is the general absence of an adequate scientific outlook with all that it connotes—the willingness to accept change, the capacity to explore new situations, and to develop appropriate methods undeterred by prejudice or preconceived ideas—that is our gravest danger to-day. To that outlook there must be joined those moral qualities, sincerity of purpose, loyalty to truth, patience, courage, humility, unselfishness and the capacity to work with others, of which neither the philosopher nor the scientific worker has a monopoly and which both have demonstrated can be consistent with the exercise of the greatest intellectual gifts.

The clash between science and the humanities or the classics is long since out of place. The noblest resources of both are needed in the task before us if true are to be sifted from false values. Means must be found of making accurate knowledge of the facts of the universe eloquent and understood of all, and equally the moral consciousness of mankind must be roused to use his knowledge to great purposes. It is only as men are willing to face the full facts of the situation, to develop new methods where they may be called for, to renounce on occasion deeply embedded habits or even ways of thought and take up the challenge of adventure which scientific advance flings down to them, that we can hope to emerge from our present difficulties, and handle successfully the many problems presented by an age of mechanism with its concomitant leisure.

For the planning and national planning thus involved for the full exploration and interpretation of the phenomena of social life, scientific outlook and method must be harmoniously linked with a vision of humanity, a sense of values, of order and of beauty which mankind has learnt to find in the individual experience or biography recorded in the humanities in great literature and art.

The Origin of Mammals

The Mammal-Like Reptiles of South Africa: and the Origin of Mammals. By Dr. Robert Broom. (Issued under the auspices of the Carnegie Corporation of New York, and the Research Board, Union of South Africa.) Pp. xvi+376. (London: H. F. and G. Witherby, 1932.) 25*s*. net.

FOR many years the fossil reptiles found in the Karroo rocks of South Africa have excited great interest because they seem to include the ancestors of mammals, or at least show how some of the early reptiles may have passed into mammals. They date back to the Permian and Triassic periods, when mammals and birds must have had their beginning; and many of them are in so remarkable a state of preservation as whole skeletons that they are most satisfactory for study. Nearly all, however, are described in small scattered papers, and some are so strange that they have been interpreted in different ways at different times by various authors, so that it is not easy to obtain a good idea of the interesting phase of reptilian evolution which they represent. Dr. Broom has thus done good service to science by preparing an authoritative summary of our present knowledge of the subject, to which he himself has contributed the greater share during the past thirty years. With the aid of a grant from the Carnegie Trust he has published a handsome volume, which will be eagerly studied by all who are interested in current biological problems.

The Karroo rocks seem to have been formed at the mouth of a great river which spread its mud over what is now South Africa for many millions of years. There were desert regions around, and most of the sandstones originated from masses of blown sand. The area was sinking, so that an immense thickness of deposits accumulated, and great changes in the reptile life are observable in the successive layers or zones. Dr. Broom briefly enumerates these changes, and shows how some of the latest Karroo reptiles are the most mammal-like, while some of the earliest are most similar to the amphibians which were presumably their ancestors. There is, however, scarcely any trace of these ancestors in South Africa, for the lowest Karroo rocks, so far as known, rarely contain remains of vertebrate animals.

The greater part of Dr. Broom's book naturally consists of a technical systematic account of the various genera and species, which are arranged in

the several large divisions that he recognises. In each case a reference is given to the original description, when the species has been described before; and when there are synonyms or expressed differences of opinion, these are always discussed. There are also some important corrections of localities assigned to certain fossils in the writings of Owen and other pioneers. The descriptions and discussions are well illustrated by a series of clear diagrams drawn by Dr. Broom himself. There are, however, no illustrations of the actual fossils, to show their state of preservation and permit any judgment as to the reliability of the conclusions based on them. Dr. Broom, indeed, considers that such illustrations are not needed in a scientific treatise, and commends the restored figures of fossils published by Traquair and Marsh; but he omits to mention that Traquair's restorations were usually accompanied by drawings of the specimens on which they were based, while Marsh's restorations are considered so unsatisfactory by later American palæontologists that they have begun to publish figures of the original specimens for reference. He even approves a "restored skull drawn from two or three specimens", without giving any account of the nature of the fragments; thus producing composite portraits, so to speak, like those in certain early works on fossil invertebrates which have caused so much confusion in stratigraphical geology, and are now being remedied by the publication of photographs of the original fossils when these can be traced. This is our only serious criticism of the book, but it bears some marks of hasty compilation, and we would add that the descriptions of the species (especially new species) would have been more useful if the locality and horizon had always been stated. A table of distribution would have been a desirable addition.

Dr. Broom summarises his results in a most interesting chapter on the origin of mammals. He discusses the range and the relationships of the several groups, and among other curious facts notes the long range in time of the Anomodonts, which had a horny beak replacing teeth. Pointing also to the Chelonians and the birds, he remarks that the horny beak is one of the "most successful adaptations ever accomplished". He adds that "all the steps by which the mammals have arisen from the reptiles seem to be connected with change of habit and change of diet, comparatively slow moving forms have given place to others with greater and greater powers of active movement". Small omnivorous and carnivorous animals have the best chance of advancement, and the little Ictidosaurians of the Upper Karroo seem to be as nearly as possible mammals.

In a concluding chapter Dr. Broom gives a sympathetic account of the discoverers and chief collectors of the Karroo fossil reptiles, all of them amateurs well occupied in other vocations. Andrew Geddes Bain, the pioneer in South African geology, was a civil engineer. He was followed by his son and J. M. Orpen, and some medical practitioners, a clergyman, a farmer, a postmaster, a gardener, and a blacksmith. Dr. Broom himself, during most of his career in South Africa, has been busily engaged in the medical profession, and could only devote his leisure to scientific research. He is to be congratulated on his remarkable success; and his progress should be stimulated by the admirable review of past achievement which he has just completed.

A. S. W.

Magical Arts and Beliefs in Europe

(1) *Witchcraft, Magic and Alchemy.* By Grillot de Givry. Translated by J. Courtenay Locke. Pp. 395 + 10 plates. (London, Bombay and Sydney: George G. Harrap and Co., Ltd., 1931.) 42*s*. net.

(2) *The Story of the Devil.* By Arturo Graf. Translated from the Italian by Edward Noble Stone; with Notes by the Translator. Pp. xiv + 296. (London: Macmillan and Co., Ltd., 1931.) 15*s*. net.

(1) EVEN if the claim that this book is unique as an iconography of witchcraft and the occult were not justified, it would still be noteworthy in any collection of works dealing with the subject of magic for the number and character of its illustrations. Three hundred and fifty figures in the text, and ten coloured plates, reproduced from carvings, drawings, paintings, prints, and manuscript or book illustrations, provide a panorama of the magical arts and beliefs in Europe from the Middle Ages to the beginning of the nineteenth century. Not only do these illustrations cover such obvious topics as the devil and his angels, the sorcerer and the witch, the alchemist, the astrologer, early users of the divining rod, and searchers after the philosopher's stone; but here are also divination and fortune telling—whether by the hand, the lines and form of the face, clairvoyance, or the cards and other material means—the tarot, the cabbala, and the talisman. The

pictures of the laboratories and apparatus of the alchemist and 'puffer' in various periods are of great interest to the historian of the development of scientific investigation.

The originals of some of the prints and other illustrations are of extreme rarity: many are in the possession of the author and other collectors; while those which are open to public inspection could be consulted only with much expenditure of time and money. Now brought together within the covers of one book and provided with an excellent running commentary, they are made accessible to every student, and their value enhanced enormously.

Not a great deal of the material collected here is connected directly with folk-lore, that is, with the belief of the folk in the stricter sense. In the early woodcuts from various sources a wizard crosses the sea by means of a spell, witches raise storms or sell winds bound by a knotted cord to sailors, and a witch draws milk from the handle of an axe stuck in a post. In passing, it may be suggested that it would be in accordance with popular belief if a sorry cow in the background were the source of the milk, rather than its condition the cause of a dearth which the witch is being asked to remedy, as the author believes.

The greater proportion of the illustrations which deal with the witch and related conceptions, however, are in what may be called the 'theological' rather than the popular tradition. They range from the Last Judgment to the Witches' Sabbath. It is not without significance that the artists' representations of the Sabbath, for example, agree down to minute detail with the 'official' description of orthodox writers. It is only in the eighteenth century, when the persecution of witches had died down, that discrepancies and fantastic details supplied by the artist's imagination begin to appear. In Spain, however, where the tradition perhaps, was stronger, Goya even at the beginning of the nineteenth century was able to maintain accuracy in detail, with startling and horrific effect. It is interesting to find that in Germany, so late as the middle of the eighteenth century, cartographers, in mapping the Hartz district, still kept up the tradition of showing the Brocken out of all proportion, and of representing on the map crowds of witches proceeding to the great celebration of the Sabbath on broomsticks and on foot.

Although an examination of those illustrations here which relate to witchcraft and attendant beliefs, when taken as a whole and in logical sequence, tends to confirm the view that the accounts of the organisation of the witches and their ceremonial, as we find them in the witchcraft persecution, were the product partly of theology, partly of imagination stimulated to excess by panic, hysteria, and psychopathic aberration, there is no doubt that they embody much that was taken from authentic popular beliefs, for which parallels can be found in the magic of primitive peoples. Sometimes these illustrations serve to emphasise such points in a way that the literature fails to do. It is interesting to note that in representations of the witches' and sorcerers' dances are cases, clearly, of the phenomena of possession which we know from other sources was rampant at times in medieval Europe. It is also made very apparent that witchcraft was closely allied to an animal cult and the werewolf belief. In a Teniers' print the witch takes on animal form as she flies up the chimney.

(2) That the devil was in the main a creation of the theologian, or perhaps it would be more correct to say that his character, attributes, and achievements were embroidered on a non-Christian concept by theological dogma, is supported by the material which has been brought together in Arturo Graf's book. The original, of which the volume now under notice is a translation, appeared so long ago as 1889. Had it been written to-day, or even a decade later than it was, the author's orientation might have been slightly different. Possibly he would have laid more emphasis upon the incorporation into Christianity of elements from the religions of the Mediterranean and the Near East, as well as on popular belief. This in no way detracts from the excellence of his work so far as it goes: but his picture would be by that the more complete in detail. That this would have modified his conception of the devil in any essential is improbable. The trend of his thought is indicated by the fact that he believed, at the time of writing, the devil was dead.

Graf's purpose was neither analytical nor controversial. He set out to give a plain descriptive account of the belief in the devil, mainly as it existed in medieval times. The belief, he held, originated in the conflict between the powers of good and evil which was the predominant element in Zoroastrianism and had been adopted by Gnostics and Manichæans. By the time of the medieval theologians, the two kingdoms of Heaven and Hell had taken their stand over against one another in the contest for the domination of the world with all the trappings and organisation in court and camp of an earthly principality. The author describes in some detail the precision with which the exact number of devils forming Satan's

legions and their organisation was determined. The character and province of each of the Princes of Darkness was appraised with no less degree of accuracy.

In the result, the Church built up a picture of the devil and his followers which in practice, if not in theory, and in the belief of the average man, elevated him to a position of influence transcending that of God. When Graf describes the activities of the devil, his frauds and violent acts, his temptations, his loves and his offspring, he exhibits the devil as a constant obsession of everyday life. He goes on to suggest that in this perverted form of religious emotionalism, which had the devil and not the deity as its central object, is to be found the explanation of such obscene practices as were attributed to the Patarini and other heretical sects, and of the witches' Sabbaths with their elaborate inverted ceremonial. Graf allows this much of reality as the basis of the witch persecution: it might equally well have originated in the leading questions formulated by the perverted imagination of the Inquisitors. In either case, it would arise from a Christian theology rather than a paganism surviving as a living force in a folk-ritual, as some would have it.

The succubus and the incubus, the defeats of the devil, the ridiculous devil and the good devil, especially the last two named, prompt further discussion, especially in relation to early forms of spirit belief, the medieval sense of humour, and the cult of the obscene as a prophylactic; but space forbids. Enough has been said to indicate the excellences as well as the limitations of a fascinating book.

The translation is admirably done, and the notes by the translator are both scholarly and helpful.

Advanced Studies in Heat

A Text Book of Heat (including Kinetic Theory of Matter, Thermodynamics, Statistical Mechanics, and Theories of Thermal Ionisation). By Prof. M. N. Saha and B. N. Srivastava. Pp. xxv + 771. (Allahabad: The Indian Press, Ltd., 1931.) n.p.

A COMPARATIVE beginner in the study of physics automatically subscribes to the time-honoured convention, which the average textbook does little to dispel, of grouping the subdivisions of that branch of science under five or six rigid headings. Some utility may reasonably be claimed for such classification, even though the insidious evil of thinking in terms of 'water-tight compartments' may not be unconnected with so primary an attempt to sub-divide knowledge of natural phenomena. The revolution initiated early in the present century by the quantum theory has been so drastic, and has been followed up by a vast field of workers eager to explore the multiplicity of paths which it brought to light, with the result that an amazing accumulation of knowledge has resulted, with which the modern physicist and chemist is expected to cope.

The elimination of the artificial boundaries within the realms of physical science, and the definite progress being made along the lines of co-ordinating and unifying our views of the mechanism of natural phenomena are strikingly apparent from a study of this up-to-date and concise treatise on the work and its outcome resulting from the revolution to which attention has just been directed. The need for a good digest of modern heat theory must have been acutely felt by the majority of advanced students, and the publication of this textbook, one of the authors of which has made extensive contributions to important aspects of the subject, is all the more welcome at the present time, inasmuch as it comprises a most comprehensive survey, conceived and carried out on broad and generous lines, of information which could only otherwise be obtained by laborious reference to a large number of special treatises and original papers.

The ordering of the subject matter shows a slight departure from the conventional. The normal content of the 'intermediate' textbook is little in evidence, and introductory chapters on thermometry and calorimetry are followed by a detailed review of the kinetic theory of matter, equations of state, and change of state. A chapter is devoted to low temperature technique and the approach to the absolute zero, after which comes a condensed survey of thermal expansion and a more detailed survey of conduction with its relation to electrical conductivity. Heat engines are reviewed in historical sequence as an introduction to the laws of thermodynamics and entropy, thermodynamical functions, equilibria of physical and chemical systems, and thermodynamics of chemical equilibria, illustrated, amongst other reactions, by the Haber process.

The section on radiation contains a complete historical review of the subject, including the development of the quantum theory, with abridged deductions of such relations as the Rayleigh-Jeans,

and Wien's laws, and a fairly complete account of Planck's epoch-making researches. It is open to question how far much of the early theoretical work on radiation might have been omitted in favour of more detailed descriptions of general modern experimental methods and technique. The new quantum mechanics quite reasonably finds no mention in the book. The account of the quantum theory is naturally followed by a survey of the older well-known anomalies and difficulties to which it formed, in so striking a manner, the key. The concluding two chapters are devoted to the Nernst heat theorem, the Einstein-Bose-Fermi statistics, and the theory of thermal ionisation in relation to the state of matter at high temperatures; an important and welcome inclusion. Certain important general deductions and tabular data are collected in an appendix. Good name and subject indexes occupy respectively 7 and 23 pages, though even the latter failed under the test of a search for 'photon', discussed in the text.

The volume as a whole is undoubtedly one of the best advanced textbooks of heat, and much attendant physical chemistry, at the present time. As stated in the preface, it is based largely on lectures to B.Sc. (Hons.) and M.Sc. students. Copious footnote references are given to original papers and special bibliographic sources of information, which extend the utility of the book to specialists and research workers. The treatment throughout is largely theoretical, while the experimental side is distinctly condensed, although the diagrams are good and moderately numerous. The somewhat cheap-looking and poor style of printing, particularly of formulæ, along with minor typographical errors, could doubtless be rectified in a succeeding edition. N. M. B.

Short Reviews

Chemical Encyclopædia: a Digest of Chemistry and its Industrial Applications. By C. T. Kingzett. Fifth edition. Pp. viii + 1014. (London: Baillière, Tindall and Cox, 1932.) 40*s*. net.

THE issue of a fifth edition is presumptive evidence that a book has filled a need, and this is certainly the case with Kingzett's digest of chemistry. We have had it on our shelves for some little time, and have found frequent opportunity to test it in the daily round of affairs. On every occasion it has provided the requisite information, generally with a reference to where the particular point can be followed up with greater detail.

Chemistry is so integral a part of every science to-day and covers in itself so vast a range that it will be of advantage to every scientific worker, not alone the chemist, to have this book to consult. The information is just what is wanted; succinct, without being lengthy, details are given as to what a compound is and what it is used for. Electrons, elements, enzymes, effluents, eggs, enamels and emulsions, all receive appropriate and illuminating paragraphs. The work has been brought right up to date, and there is evidence of meticulous care on every page. The cross-references are very complete. A useful feature is the indexing of substances with proprietary names, such as carbosil, carboraffin, carboxide, with an indication of what they represent; in the past it has often been difficult to identify these.

Modern Chemistry: the Romance of Modern Chemical Discoveries. By Dr. Frederick Prescott. Pp. xiii + 370 + 39 plates. (London: Sampson Low, Marston and Co., Ltd., n.d.) 12*s*. 6*d*. net.

THE object of Dr. Prescott's book is stated in the preface to be that of providing an account of some of the more important and interesting discoveries of chemical science and of their applications which shall be suitable for readers who, although aware of the importance of the science in daily life, have neither the time nor the inclination for mastering the details of the subject.

The first part deals with the scope and development of chemistry, including a concise history of early chemistry which is not always in agreement with modern knowledge, and a sketch of modern views on the atomic theory which contains a few inaccuracies, as on p. 73 where the disintegration of atoms is said to have been accomplished by means of X-rays. On the whole, however, these sections are accurate and clearly written. The applications of electricity, metals and alloys, fuels and illuminants, nitrogen fixation (which the author still calls "the nitrogen problem" and encumbers with descriptions of obsolete processes), explosives, cellulose products, colour chemistry (which is dealt with in some detail, structural formulæ written in a curious and inconsistently used script, and technical expressions being employed), "harnessing micro-organisms", and "chemistry versus disease", are the remaining sections of the book. J. R. P.

The Dorado. By John W. Hills and G. H. Harrisson. Pp. vii + 190 + 22 plates. (London: Philip Allan and Co., Ltd., 1932.) 10*s*. 6*d*. net.

THE dorado or golden salmon is, as the authors tell us, not even a relative of the well-known aristocratic fish, but one of what they happily call the "rather bourgeois" family of the Characinidæ, particularly characteristic of the fresh waters of South America, where they occupy much the same place as the carp family do in the Old World. The dorado is "the great commoner" of this characinid clan; very like the salmon in general appearance,

and even in possessing, like it, pink and palatable flesh; it is more heavily built and shows itself a stronger fighter when hooked, though less resourceful. In size also it corresponds roughly with the salmon; the authors' best fish was forty-six pounds in weight, but monsters of a hundred pounds were heard of. Old-gold in colour, with red fins and tail-stripe, the dorado surpasses the true salmon in splendour; but apparently all four species of its genus, *Salminus*, share the name. The authors' adventures in pursuit of this golden quarry are well told and well illustrated, and notes on other fish and on the bird life encountered help to make up a very readable and instructive volume.

One Hundred Years in Yosemite: the Romantic Story of Early Human Affairs in the Central Sierra Nevada. By Carl Parcher Russell. Pp. xvi + 242 + 29 plates. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1932.) 20*s*. net.

THIS attractive volume has inside its covers a map of the Yosemite National Park and adjacent regions and its frontispiece is a fine photographic portrait of Maria Lebrado, the last of the original Yosemite Indians, who died, at an age of more than ninety years, only last year. Full details of the warlike and other relations of the local Indians and whites are given, and it is plain that though the Yosemites were a troublesome tribe, the behaviour of the more advanced race was often discreditable. Most lamentable was the murder by a white man, of Major James Savage, one of those remarkable personalities who are able to control and win the affections of members of more backward peoples. No portrait of him appears to be extant, but those of some other celebrities connected with the development of the region are included, and a chronology with sources and bibliography of the history of human events in the Yosemite adds value to an already comprehensive work.

A Textbook of Practical Astronomy: primarily for Engineering Students. By Prof. J. J. Nassau. (McGraw-Hill Astronomical Series.) Pp. x + 226. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1932.) 18*s*. net.

ALTHOUGH primarily intended for students in civil engineering, this book is admirably adapted for a larger class of readers. A book on practical astronomy must necessarily take a lot of the theoretical arguments for granted, but even so, the author has succeeded in incorporating a sufficiently adequate amount of theoretical matter.

The principal instruments described are the theodolite, sextant, and zenith telescope, and the practical problems discussed concern the determination of latitude, longitude, azimuth and time. The methods of reducing observations are carefully described and illustrated by numerous examples. A feature of the book is the excellent series of diagrams. The only weak part is the first chapter, which is rather sketchily written (there we read, for example, that planets are opaque *spheres*). The book can be warmly recommended as an introduction to elementary practical astronomy.

The Elements of Astronomy. By Dr. D. N. Mallik. Second edition, revised. Pp. iii + 234. (Cambridge: At the University Press, 1932.) 14*s*. net.

THIS book treats of the usual subjects of elementary astronomy and, on the whole, it presents a satisfactory introduction for readers whose mathematical attainments are slight. Unfortunately, some parts of the book savour too much of a nineteenth century atmosphere. For example, the method of measuring the solar parallax by means of transits of Venus is fully described but there is no reference to the present direct practical method associated with observations of Eros; an example on 'time' has reference to an observation made in 1865 and the author appears to be unaware of the far-reaching alterations made in the almanacs in 1925, for he states that the Equation of Time is given in the *Nautical Almanac* for Greenwich Mean Noon. A second edition ought to have embodied the latest changes in astronomical practice and methods. The book is illustrated with numerous well-drawn diagrams (No. 34 is upside down). An interesting feature is the historical introduction with its background of ancient Hindu and Chinese astronomy.

Walter Leaf, 1852–1927: some Chapters of Autobiography. With a Memoir by Charlotte M. Leaf. Pp. x + 338 + 8 plates. (London: John Murray, 1932.) 10*s*. 6*d*. net.

CLASSICAL distinction, authority in the banking world, and social services, provide the threads of interest. Incidentally, we learn that Leaf's entry to Harrow School (1866) coincided with the appointment of the first science master, George Griffith. Again, the "new game of lawn tennis" was played at Cambridge about 1873. The court was the grass between the library of Trinity and the river. A badminton net, toy racquets, and parti-coloured indiarubber balls were obtained at the toy shops—the earliest apparatus used in the early days of a world game.

A Pocket Atlas and Text-Book of the Fundus Oculi. By Dr. G. Lindsay Johnson. Second edition, revised and enlarged. Pp. ix + 215 + 28 plates. (London: Adlard and Son, Ltd., 1931.) 12*s*. 6*d*. net.

THE revised and enlarged edition of this eminently useful guide to the uses of the ophthalmoscope will be welcomed by medical students and young practitioners. It is illustrated by a large series of Mr. Arthur Head's beautiful coloured drawings of the fundus, and the text is clear and easily understood.

Entomological Research in the Marquesas Islands

By Dr. HUGH SCOTT

THE Marquesas are the first islands chosen for intensive study by the Pacific Entomological Survey, which is being conducted jointly by the Bernice P. Bishop Museum, Honolulu, the Hawaiian Sugar Planters' Association, and other bodies. A preliminary general account of results by E. P. Mumford, director of the Survey, and A. M. Adamson, entitled "Entomological Researches in the Marquesas Islands", was prepared for the fifth International Congress of Entomology, in Paris in July 1932, and a few typewritten copies have been distributed.

Field-work was carried on by these two writers and others during the three years, 1929–31. Collections were formed of all terrestrial animals except birds (which were already fairly well known), all fresh-water animals, and plants (the last on account of their association with the insect fauna). Records were made of geographical, meteorological and other observations. Previous entomological work, the most important of which is based on the collections made by the *St. George* expedition, is being taken into consideration. The publication by the Bernice P. Bishop Museum of an extensive series of systematic reports has been begun, and an introduction is being prepared by Messrs. Mumford and Adamson.

The Marquesas are among the most isolated islands in the world, and are actually farther from continental land than any other comparable archipelago. Situated in 7°–11° S. lat. and 138°–141° W. long., they extend from north-west to south-east (the same direction as the Hawaiian and other Pacific groups) over some 230 miles. Their total area is about 500 square miles (that is, roughly one-fourteenth that of the Hawaiian Islands). All are high volcanic islands, almost entirely devoid of fringing coral reefs. The six larger islands reach an altitude of 3000–4000 ft.

Since the advent of Europeans, great changes have taken place, and are still rapidly happening, in the endemic flora and fauna. The familiar melancholy tale has to be told. Deforestation and denudation, for which sheep and other domestic animals are largely responsible, are far advanced. In the lower islands, the very interesting insect fauna seems doomed to extinction. In the higher islands, deforestation has affected much less the cloud zone above 2000 ft., where the moisture of the trade winds is precipitated as a heavy rainfall. But, even at these altitudes, the leeward slopes are relatively dry, and semi-arid *terres désertes*, denuded by grazing animals, occur. Moreover, the high forests are being invaded by a recently imported grass (*Paspalum conjugatum*), and a now cosmopolitan marauding ant, *Pheidole megacephala*, is an active agent of destruction.

The insect fauna has all the characters associated with isolated oceanic islands, *inter alia*, predominance of small size, dull colouring and obscure habitat; absence of many families and super-families, and of some entire orders; and disproportionate development of a few genera. Aquatic groups of insects and other fresh-water animals (as well as fresh-water plants) are poorly represented.

Groups entirely absent comprise the orders Plecoptera, Trichoptera, Ephemeroptera and Mecoptera (the first three of which are aquatic in their early stages); all the aquatic Hemiptera-Heteroptera constituting the sub-order Cryptocerata; among Hemiptera-Homoptera, the Cicadidæ, Cercopidæ, Membracidæ, aphids, and many families of Fulgoroidea; most families of Neuroptera, many great families of Coleoptera (for example, the entire lamellicorn series), many families of Diptera; and, in Hymenoptera, the sub-order Symphyta (sawflies, etc.) and most families of aculeates.

The authors regard these gaps in the fauna as strong evidence against the existence in past ages of extensive land areas in the Pacific. On the whole, this conclusion is probably right, but it may be pointed out that some of these groups are also absent from the faunas of islands not of volcanic and purely oceanic origin. Plecoptera, Mecoptera and Hymenoptera Symphyta are absent from the fauna of the Seychelles,* an ancient granitic archipelago, believed to be the remains of a much larger land, even if not of definitely continental origin. These groups are also, so far as is known, very poorly represented in Ceylon. Allowance must be made for their being apparently weakly developed in the tropics as a whole, both continents and islands, as compared with their much richer development in temperate latitudes.

Other features mentioned above, namely predominance of small size and dull colouring and weak representation of aquatic groups, are also characteristic of the fauna of the Seychelles. But disproportionately developed genera are much more numerous in the volcanic archipelagoes, and only of exceptional occurrence in the Seychelles.

Among the components of the Marquesan fauna one of the most interesting is the genus *Proterhinus* (Coleoptera, Rhynchophora). Originally discovered in the Hawaiian Islands, where more than 150 endemic species exist, it was made the sole genus of a new family. Afterwards a single species was found in Samoa and one in the Phœnix Islands, and two in the Marquesas must now be added. The genus most closely related to *Proterhinus* is *Aglycyderes*, of which one species in the Canary Islands and two in New Zealand are known†.

* See an abstract of "Summary and General Conclusions Regarding the Insect-Fauna of the Seychelles and Adjacent Islands", by Hugh Scott, (*Proc. Linn. Soc.*, Session 144, pp. 136–140, 1931–32).

† In several textbooks New Caledonia is included in the range of *Aglycyderes*, but I cannot trace any published description of a species in that country.

These two genera are now considered to form a single family. The distribution of *Proterhinus*, centred in Hawaii and with outlying species in other Pacific islands, is comprehensible, as is also the occurrence of related forms in New Zealand. But no explanation suggests itself for the existence of another relative in the Canaries, when no representative of the family has come to light in any other part of the world—even where the fauna has been intensively collected.

The degree of endemism is very high. Excluding wide-ranging forms, few or no species are common to the Marquesas and Hawaii or Samoa, the nearest high islands of which the fauna is well enough known for comparison. Among species the degree of endemism is probably lower than in Hawaii, but of the same order (that is, approaching 80 per cent); among genera it is much lower.

The proportion of endemic species restricted to a single island is apparently higher than in Samoa and of the same order as in Hawaii. For example, there is, as in many remote islands, a great development of endemic Curculionidæ, and, in the otiorrhynchine section, the number and diversity of species, each restricted to a single island, indicate that the archipelago is of considerable age. Like phenomena are noted among the Hemiptera-Homoptera, while, on the other hand, in one family of Hemiptera-Heteroptera a genus has developed into many closely allied endemic species, some of which range over several islands. Possibly these latter forms originated too recently to have diverged into separate species. It is too early to state whether any evidence is forthcoming of an increase in the habitable age of the islands from south-east to north-west, like that of which there is some indication in the Hawaiian archipelago.

Nor are generalisations as to the origin of the fauna yet possible; for, some groups of animals exhibit close relationships with the fauna of Hawaii, others with that of the south central Pacific islands lying to the south-west. Among the former are the Hemiptera-Homoptera, among the latter the Hemiptera-Heteroptera, and the endemic birds and land snails, which have little in common with those of Hawaii. Botanists have stressed the existence of important, though secondary, affinities between the Marquesan and Hawaiian floras.

Deductions bearing on past land connexions in the Pacific are also left until the fauna has been fully worked out. While the almost entire absence of coral reefs has been attributed to rapid subsidence, alternating elevation and subsidence have also been postulated. In either case, the number of species restricted to a single island indicates that the individual islands have been separated for a long period, if time be regarded in terms of what is needed for the formation of species.

The sections on association of endemic insects and plants, and the bearing of the investigation on agricultural and medical problems, cannot be discussed here. Enough has been written to show the nature of the questions discussed. The Survey may be congratulated on an excellent start.

Some Problems of Food Preservation

THE problems involved in the freezing, storage and transport of New Zealand lamb have recently been examined by the Food Investigation Board, in co-operation with the Empire Marketing Board, the New Zealand Department of Scientific and Industrial Research, the New Zealand Meat Producers' Board and the New Zealand Tonnage Committee representing the shipping lines trading between Great Britain and New Zealand.[1] The investigation involved an analysis of the physical conditions in the various storage chambers through which the meat passed and an examination of the effects of the environment on the quality and appearance of the carcases, as estimated from the loss of 'bloom'. Bloom is the freshly-killed appearance of the meat and is dependent upon the appearance of the superficial tissues, the exposed muscle, fat and connective tissue. It is affected by the following factors: the rate of cooling and freezing, which determines the opacity of the superficial connective tissue and, indirectly, the colour of the visible muscle; the amount of drying, excessive desiccation producing marked loss of colour in the muscle; the formation of methæmoglobin from hæmoglobin on prolonged storage, that conversion being hastened by sweating; and finally, excessive sweating, which also results in swelling of the connective tissue fibres with increase in their opacity.

When meat is frozen, the structure of the muscle is changed, so that on thawing it is not so resilient and there is a leakage of free fluid, usually referred to as 'drip'. Freezing probably denatures certain of the proteins so that they lose some of their power to hold water. At a temperature constantly below $-8°$ C. other changes, such as those due to autolysis, microbial growth or hydrolysis and oxidation of the fat, are only slight. It is therefore the alterations in the physical properties of the meat which are of the most importance. They are indicated by loss of weight as well as by loss of bloom.

The survey has shown that there is no need for radical alterations of technique, although improvements at each stage of the chain of treatment are possible. It has been found that bloom is affected not only by the immediate ante-mortem treatment of the sheep but also by such factors as breed, diet, age at killing, etc. Southdown crosses were found to have a good initial bloom and that was correlated with a higher concentration of hæmoglobin in the superficial muscle; older animals had a better bloom than younger of the same breed. Starvation prior to slaughter had

little effect on bloom but strenuous exercise was definitely deleterious, the superficial muscle being of a dark reddish-grey colour. The important conclusion is drawn that, within limits, carcases having the superior initial bloom will maintain this superiority throughout the subsequent chain of treatment.

After slaughter the carcases are cooled, preferably at a low temperature (12° C.), and in air near saturation point. Hanging for 10–12 hours should precede freezing. At this temperature the rate and extent of loss of weight during hanging are reduced, so that the superficial desiccation is also less. The rate of loss of weight on subsequent freezing is also lower with an adequate period of cooling.

Each chain in the passage of the meat from the freezing chambers in New Zealand to the cold stores in London was examined in detail. The advantages and disadvantages of the different systems of refrigeration are pointed out. The danger points are the transport from store to ship in New Zealand and from ship to store in Great Britain. Recommendations to minimise the delays at these points in the chain are given in the report: too long exposure of the carcases to a high temperature results in softening and sweating. It was found that the average loss of weight during cooling, freezing, 28 days storage in New Zealand, ocean transport and 28 days storage in Great Britain was 3·65 per cent in prime quality lambs and slightly greater in second quality carcases. The longer carcases are stored the greater is the loss of weight and, therefore, of bloom. Since loss of weight occurs to some extent even under the best conditions of storage, it appears necessary, to prevent any loss of weight or bloom, to cover the carcases with bags impermeable to aqueous vapour. The ideal bag, however, has still to be evolved.

Another problem of cold storage is the prevention of the yellowing of the abdominal fat in rabbits. Even when kept at a temperature of −10° to −12° C., the superficial fat, in addition to becoming rancid, acquires on its exposed surface a pronounced yellow colour, varying in tint from light yellow to dark orange. The discoloration extends to a depth of a few millimetres and in advanced stages the yellow fat is wax-like in nature and can generally be peeled off from the white fat beneath. The period between the killing of the rabbits in Australia and New Zealand and their marketing in Great Britain varies but is on the average 4–5 months. The longer the storage the more frequently is the yellowing found.

J. R. Vickery has recently carried out experiments on the nature and cause of this yellowing: the results obtained have indicated the measures which can be adopted to prevent it.[2] It was found that the rate of development of yellowing during storage in the frozen condition was dependent, within limits, upon the duration and temperature of storage in the pre-freezing period: thus storage for two days at atmospheric temperature prior to freezing enhanced the yellowing to a degree approximately equivalent to one month's storage at −5° C. The intensity and depth of penetration of the yellowness were proportional to the duration of storage in the frozen condition at a given temperature, and were greater the higher the temperature. At −10·5° C. the market value of the rabbits is affected within three to five months according to the nature of the pre-freezing treatment. At −18° C. yellowing is almost eliminated.

The yellow material accompanies the soaps on saponification of the fat and can be separated from the fatty acids by the use of ice-cold petroleum ether in which it is insoluble. It apparently has its origin in the oxidation of the linoleate glycerides under the influence of an oxidase present in the fatty tissue, the action of which is markedly accelerated by the presence of moisture and hæmoglobin. The pigment is probably an unsaturated ketonic compound.

The measures required to prevent yellowing are, therefore, the exclusion of oxygen and hæmoglobin, shortening of the time of storage and storage at a lower temperature. Air can be excluded from the abdominal fat by covering it with the muscle of the abdominal wall, hæmoglobin by thorough bleeding of the animals and cleaning the fat of all superficial blood: but a lower temperature of storage will still be necessary to prevent appreciable yellowing over periods of about six months.

Dr. Vickery also made a few observations on the development of rancidity in the fat of rabbits. It was found to develop on storage much more rapidly than is usually the case with other animals: its onset can be retarded by excluding air from the fat and storage at temperatures below −10·5° C., at which temperature rancidity may be expected in five months.

Further information on problems of food preservation can be obtained from the Index to the literature issued twice a year by the Low Temperature Research Station. The first number of vol. 4 contains a review of noteworthy developments during 1930-31,[3] to some of which brief reference may be made. Troy and Sharp have investigated the condition of lactose in dried milk, condensed milk and ice-cream. In dehydrated milk the lactose is present as an equilibrium mixture of non-crystalline α- and β-lactose; when milk is dried slowly below 50° C., lactose crystallises in the α-hydrate form. These facts are considered to explain the caking of milk powder and 'sandiness' in ice-cream. Parisi has shown that the velocity of crystallisation depends on the velocity of transformation between α- and β-lactose, and is influenced considerably by the hydrogen ion concentration of the solution. Lampitt and Bushill have shown that fat in milk dried by the roller-process can nearly all be removed by direct extraction with a solvent, while only a small proportion can be extracted in this way from spray-dried milk. The difference is attributed to the condition of the lactose; its crystallisation appears to result in 'freeing' of fat.

Slight hydrogenation of the fat has been found of value in the case of a number of foodstuffs: it prevents rancidity in tallow and lard; it stabilises the fat in butter without destroying its flavour; it bleaches palm oil without hardening it; and finally, in the case of cacao-butter, it prevents the 'blooming' of chocolates.

Morgan, Field and Nichols have found that the vitamin C content of prunes and apricots need not be reduced by dehydration or treatment with sulphur dioxide when the processes are carried out under properly controlled conditions. Clow and Marlatt state that the vitamin C content of tomatoes is the same whether ripening occurs in the field, in the greenhouse or is brought about artificially with the aid of ethylene. It has been shown by Kohman, Eddy and Zall that considerable loss of vitamin C and some loss of vitamin B occur in the canning of tomatoes in the presence of air: in steam this loss is not observed. Vitamin A is the most, and vitamin C the least stable. To preserve the vitamins it is essential to guard against oxidation during canning.

Morris and Bryan have found that the method of manufacture of steel may have a considerable influence on its rate of corrosion. In solutions of low acidity the main points of attack are the pits and seams of the tin, whilst in those of high acidity, the exposed portions of the tin are particularly liable to corrosion. It is recommended that citric acid be added to fruit of low acidity, that the sugar used be free from sulphur compounds (which have a considerable influence on the corrosion of tins) and that beet sugar be used, or agar added to inhibit corrosion.

New Tank at the National Physical Laboratory

ON November 18, in the presence of a large gathering of naval architects, shipowners, shipbuilders, engineers and others, Mr. Stanley Baldwin, Lord President of the Council, opened the New Tank at the William Froude Laboratory, which forms a part of the National Physical Laboratory, Teddington. The New Tank has been built by the Government at a cost of £45,000 to meet the increased demand for model tests of ships' hulls, propellers and rudders, and like the Alfred Yarrow Tank, will be used in connexion with work for ships of the mercantile marine.

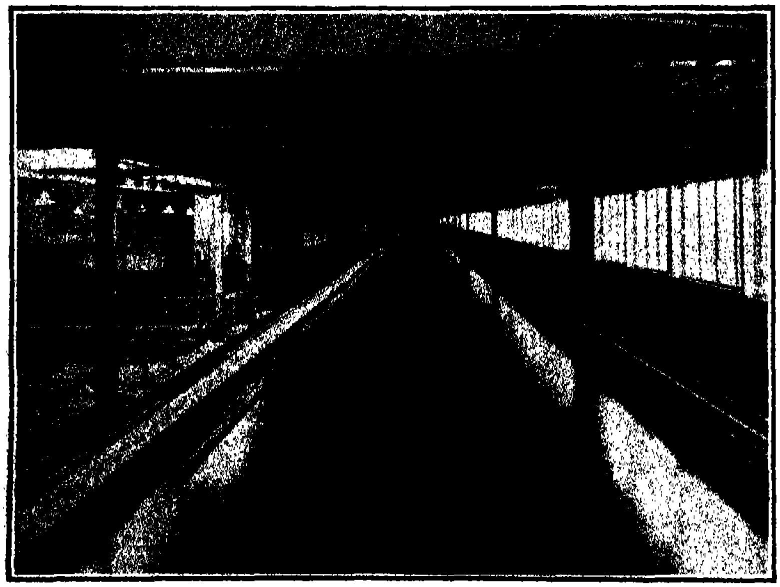

FIG. 1. The New Tank at the William Froude Laboratory

Referring to the work done in the Tank given to the Laboratory in 1910 by Sir Alfred Yarrow, Mr. Baldwin remarked that, in 1928–29 it had become impossible, though the whole staff of the Laboratory was working overtime, to comply with all the requests made for assistance by shipbuilding firms. During the years 1927–1930, 188 designs of hulls were tested in the Tank and it was possible to show how designs could be improved in no fewer than 114 cases. Among the results obtained, and adopted in the shipbuilding industry largely through comprehensive researches in the Yarrow Tank are the introduction of the 'cruiser stern' on ordinary mercantile vessels, the introduction of 'aerofoil' types of propellers, the change of rake now common in single-screw ships and the use of a central fin on this type of ship to control inflow into the propeller.

At the conclusion of his address, Mr. Baldwin went aboard the carriage of the New Tank and watched an experiment with the new equipment for testing the efficiency of propellers working in open water. Visitors present also had an opportunity of witnessing this and other demonstrations. A number of model hulls together with their recording apparatus were on exhibition, and with these were the drawings of the projected Propeller Tunnel, the cost of which (£5,000) is being defrayed by Sir James Lithgow.

The New Tank (Fig. 1) consists of a monolithic ferro-concrete water basin 678 ft. long over all and 20 ft. wide at the water surface. The depth

of water is 9 ft. for a distance of 446 ft. From this point the bottom slopes upwards gently for 36 ft. to the shallow end, 177 ft. long, where the depth of water is only 2 ft. The tank bottom and walls, the foundations of which are entirely separate from those of the building, were built in 20 ft. sections separated by 3 ft. gaps, which were filled in after the adjacent sections had set and hardened.

The carriage (Fig. 2) consists of a light frame structure of mild steel weighing approximately 10,000 lb. including its equipment. The rails on which it runs are 20½ ft. centre to centre. They were machined top and bottom before being fixed to the cast-iron longitudinal sleepers, and are exactly parallel with the surface of the water. The carriage is driven by two 56 h.p. electric motors at speeds of 2–30 ft. a second, and is brought to rest by slipper-brakes and a brake rail, operated by compressed air on the principle of the Westinghouse brake.

The control gear for the carriage is located at the side of the Tank, but should the current fail during the course of an experiment, the carriage is automatically brought to rest. In the central portion of the carriage there is an open well about 10 ft. by 4 ft. within which the testing apparatus is erected; just beneath this well the model floats in the water. In some cases the recording apparatus is placed in the models themselves, which are, of course, as usual, made of wax.

The history of experiments in Great Britain on the resistance of ships' models goes back to the pioneering work of Mark Beaufoy (1764–1827), David Napier (1790–1869), the Scotts of Greenock, the Halls of Aberdeen and others, but, as Elgar said in his Forrest Lecture in 1907: "The practical solution of the speed problem was effected by the late Mr. William Froude when he discovered the law of similitude or comparison which enables the resistance of a model, as ascertained by experiment, to be used for calculating the resistance of a model upon a different scale, or that of a full-sized ship of similar form."

Froude was born in Devonshire on November 28, 1810, and died at Simon's Town, South Africa, on May 4, 1879. After graduating at Oxford, he spent several years on railway construction and served under Brunel on the Bristol and Exeter Railway. In 1856, when Brunel was engaged with the building of the steamship *Great Eastern*, he asked Froude to investigate the motion of a ship among waves. From that inquiry Froude was led on to the study of problems akin to it, and through his experiments on towed models, the Admiralty, in spite of many adverse opinions, in 1870 constructed the historic experimental tank at Chelston Cross, Torquay, where Froude had settled. To-day there are more than a score of experimental tanks in existence and every one of them is a monument to the genius and work of Froude. The investigations carried out by Froude at Torquay, and later on at Haslar by his son, R. E. Froude (1846–1924) nearly all related

FIG. 2. The carriage of the New Tank

to warships. But just as the credit for the inauguration of the first official tank belongs to Froude, so the credit for the construction of the first tank by private enterprise belongs to William Denny (1847–1887), whose tragic death at forty years of age removed one of the foremost advocates of model experiments. In 1875 Denny sent Froude the lines of the S.S. *Merkara*, built at the Leven shipyard, Dumbarton, to enable him to make trials with a model for comparison with those already obtained with the ship herself. With permission of the Admiralty, this was carried out. Six years later, Denny began the construction of a tank at the Leven shipyard and this is now the oldest in existence devoted to mercantile work. On its facade it has borne for 49 years an inscription to Froude "the greatest of experimenters and investigators in hydrodynamics".

In his papers, his speeches and his letters, Denny did all within his power to convince his fellow shipbuilders of the utility of experimental tanks, and in 1884 wrote: "The truth is that of all the problems about a steamship the only one at the present moment incapable of being solved by *à priori* methods in extreme cases is that of speed and power. No ability and no training will enable even the most skilful naval architect to overcome the want of an experimental tank in coping with these questions."

Denny's was often a 'voice crying in the wilderness', but to-day there are few shipbuilders or shipowners who do not realise the value of the work done in such tanks as that opened by Mr. Baldwin, and none whose work is not influenced by it.

News and Views

Comptroller-General of Patents

AT the end of this month Sir William Jarratt, the Comptroller-General of Patents, Designs and Trade Marks, is retiring from the Patent Office after thirty-eight years service and six years of the comptrollership. He was educated at the Royal College of Science and Trinity College, Cambridge, where he obtained a first class in the Natural Science Tripos, and a first class in the Mathematical Tripos; he was called to the Bar of the Middle Temple in 1910. Sir William has done much to enhance the high reputation of this great Government department and has been prominently associated with important developments in patent law. In view of the growing world-wide importance of broadcasting, it will also be gratefully remembered by all authors and composers that it was mainly owing to Sir William Jarratt's intervention at the Copyright Conference in Rome 1928 that there was inserted in the Copyright Convention the article "11 bis" ensuring that "Authors of literary and artistic works shall enjoy the exclusive right of authorizing the communication of their works to the public by radiocommunication".

WHILE regretting that Sir William Jarratt will not be at the helm to steer the initial course of the new Patents and Designs Act, from which so much is expected and which owes so much to his inspiration and labours, we are glad to be able to state that he is not retiring entirely from public life, and that as the secretary of the Trade Marks, Patents, and Designs Federation Ltd., he will still be able to utilise his great knowledge and experience in the same field. This Federation is a body devoted to promoting and securing mutual support and co-operation amongst traders in the British Empire and foreign countries in all matters relating to the protection of trade marks, patents, designs and analogous rights, and the suppression of unfair trade competition. Sir William's successor in the Patent Office will be Dr. Mark Frank Lindley. Dr. Lindley is a doctor of laws of the University of London and a bachelor of science with distinction in physics; he is a barrister-at-law of the Middle Temple and author of a standard work on "The Acquisition and Government of Backward Territory in International Law". Dr. Lindley, like Sir William Jarratt, combines scientific with legal attainments and has followed him through the ranks of the examining staff of the Patent Office, and the assistant comptrollership, to the comptrollership. It is very satisfactory to scientific men and to all those connected with patents in Great Britain, to find that the practice has again been followed of appointing a man with scientific as well as legal training to the comptrollership of the Patent Office.

Sir Aldo Castellani

SIR ALDO CASTELLANI, who has been appointed to succeed the late Sir Ronald Ross as director-in-chief of the Ross Institute for Tropical Diseases, has rendered long and distinguished services to tropical medicine. He is lecturer on mycology and mycotic disease at the London School of Hygiene and Tropical Medicine, professor of tropical medicine at the State University of Louisiana and also at the Royal University of Rome, so that the direct influence of his knowledge and experience extends to several centres of teaching and research. In regard to the large field of his activities, and in the number of his contributions to medical literature, Sir Aldo has had a remarkable career. He graduated at the University of Florence and continued his studies at Bonn and the Lister Institute, went to Uganda in 1902 on the invitation of the Foreign Office to investigate sleeping sickness, then was appointed by the Secretary of State for the Colonies to the Ceylon Medical School and afterwards went to Naples for a time to occupy a chair in the Royal University, which he resigned in 1918 to join Sir Patrick Manson on the staff of the London School of Tropical Medicine. He thus possesses the highest qualifications to influence the work and promote the development of the Ross Institute.

Anniversary Meeting of the Royal Society

IT is perhaps worth while to recall that in 1832—one hundred years ago—the proceedings at the anniversary meeting of the Royal Society on St. Andrew's Day were conducted by H.R.H. the Duke of Sussex, as president of the Society. Two awards of the Copley medal were made, and Michael Faraday received one of them. The second recipient (by deputy) was Siméon Denis Poisson, the eminent French mathematician, in recognition of his treatise "Nouvelle Théorie de l'Action Capillaire". He had been elected a foreign member in 1818, along with Baron Prony, Arago, Nathaniel Bowditch, and the Abbé Haüy. Poisson was born in 1781, and he died at Paris in 1840. He was associated with the Ecole Polytechnique there for nearly forty years, and he will be remembered as a prolific and illuminating writer in mathematics, physics, and astronomy. It was on this occasion that an announcement was made that following the example of the Paris Academy of Sciences, the Royal Society would in future admit no paper into its *Transactions* which had not been previously submitted to the consideration of at least two members of the Council best acquainted with the subject under discussion. The Society's roll of membership at the period in question appears to have comprised 11 royal personages, 45 foreign members, and 692 home fellows, a total of 748. In accordance with custom and following the afternoon's proceedings the fellows of the Society dined together at the Crown and Anchor tavern, the Duke of Sussex being in the chair.

The Pacific Entomological Survey

ABOUT four years ago, certain institutions in the Hawaiian Islands, including the Bernice P. Bishop Museum, the University of Hawaii, the Sugar Planters' Association and the Pineapple Growers'

Association, organised the above-named Survey for the purpose of exploring thoroughly and studying the various island groups in the South Pacific, especially as regards their insect fauna. It was felt that this was a most necessary piece of work, seeing that the islands are being rapidly changed in regard to both fauna and flora, owing to the introduction of foreign plants and animals. It was also believed that the information gained would not only be most valuable from a scientific point of view but also extremely useful in a practical way. The first part of the work, the survey of the Marquesas Islands, has been done, and the detailed results are now being published by the Bernice P. Bishop Museum, Honolulu. Reference is made elsewhere in this issue (p. 797) to a preliminary general account of the work which has been prepared by Messrs. E. P. Mumford and A. M. Adamson. The finances for carrying on this work have been mainly advanced by the planters' associations. Within the last year, however, these organisations have suffered heavy losses which have made it impossible for them to bear the entire load of continuing the task. The Survey is, therefore, now making an effort to gain financial assistance from other quarters. In view of the splendid work which has already been done and of the very great need for continuing the Survey, it is hoped that this important piece of scientific and practical work will not have to be abandoned.

China and American Scientific Expeditions

BY courtesy of Dr. Chang Chi, chairman of the Chinese National Commission for the Preservation of Antiquities, we have received a copy of a letter dated September 24 which was addressed by the Commission to the American Museum of Natural History, New York, and covering a statement of its position in relation to the Central Asiatic Expedition of the Museum. It will be remembered that this expedition, which has been engaged in palæontological and archæological investigation in Inner Mongolia since 1922 under Dr. Roy Chapman Andrews, came to an end with the season of 1930, after which date no further permit was to be issued by the Chinese authorities. In the covering letter, Dr. Chang Chi, writing on behalf of the Commission, describes the interruption of the work of the expedition as "a most unfortunate breach in the cultural relations between China and the United States", and expresses his own regret that negotiations should have been broken off largely for personal reasons. At the same time, he reaffirms the readiness of the Commission "to promote scientific co-operation, if proposed on a fair basis". The covering letter also refers to an editorial article in the American-owned and edited *China Weekly Review* dated September 10, of which also we have received a copy. It consists largely of a personal attack on Dr. Andrews. This attack, or rather parts of it, the Commission regards as mainly irrelevant, nor does it endorse all the views expressed in the article, although it holds them significant as voicing the views of foreigners resident in China.

THE statement addressed by the Chinese Commission to the American Museum of Natural History, in addition to defining its attitude in the situation which has arisen from past activities of the American expedition and its members, declares that it is "ready to consider or submit to the proper higher authority or refer to the proper Chinese scientific institution any proposal of Sino-American co-operation for scientific exposition, despite any possible existing personal misunderstanding". It recites the terms of the agreement with Dr. Andrews of March, 1930, which, while safeguarding "Chinese interest and participation in this important scientific enterprise", assigned to the American Museum the bulk of the specimens obtained by the expedition, requiring only the return to China of representative duplicate fossils and two casts of unique specimens; and it claims to have voiced Chinese public opinion in 1928 when objecting to Dr. Andrews's activities in making archæological and palæontological investigations under cover of a hunting passport. The chief point in the memorandum, however, is the question of Dr. Andrews's recent attitude. It is stated that after repeated assurances from him that the expedition of 1930 would be final, a letter of application for a further permit for 1931 was received from him, and that without any interview with any member of the Commission. Further, in recent statements, for which he is presumed to be responsible, politics have been imported into a scientific question with the object of forcing a concession from the Chinese Government by political influence. Thus not only has the friendly co-operation with the American Museum of Natural History been interrupted, but also mutual misunderstanding has arisen between the American and Chinese peoples as to their respective attitudes.

International Commission on the Teaching of Mathematics

THIS body, constituted at the Congress of Mathematicians at Rome in 1908, had secured by 1914 the adherence of twenty-eight countries, and had evoked a large mass of valuable reports, of which those for the British Isles formed two volumes of Special Reports issued by the Board of Education in 1912. The decision to revive the dormant Commission was taken at Bologna in 1928, and this year has seen a resumption of activities, culminating in two sessions during the Congress of Mathematicians at Zurich. Prof. Hadamard of Paris succeeds Prof. D. E. Smith of New York, who has been president of the Commission since the death of Klein. The secretary is Prof. Fehr of Geneva. Though anxious to co-operate, the Board of Education is unable to play the same leading part as before the War, and the Council of the Mathematical Association has agreed to take over responsibility for the English Sub-Commission, at least until the Oslo Congress of 1936. There will again be three Commissioners, who will be assisted by special committees when reports are to be prepared. The commissioners appointed are Prof. E. H. Neville, who is on the Central Committee of the Commission, Sir Percy Nunn, and Dr. D. M. Wrinch. Reports will be published in the *Mathematical Gazette*.

Growth of Industrial Organisations

IN the second of the series of lectures on industrial affairs at the Imperial College of Science and Technology, Mr. Austin Hopkinson discussed the advantages of the small industrial organisation. In his submission, there is no evidence that increasing the size of an industrial concern leads normally to an increase in efficiency; indeed history shows that most very large organisations of this type have soon become unstable, and their collapse has led to the loss of immense amounts of capital. A distinction should be drawn, however, between natural and artificial expansion. A limit to natural expansion by internal growth or by absorption of less efficient competitors is set only by the managerial capacity of individuals, and the ideal size cannot be expressed therefore by any simple formula such as statisticians have attempted to devise. When for any reason, however, a concern is expanded artificially beyond this limit, the expedients resorted to in attempts to establish financial stability are likely to be contrary to the interests of the community as a whole. The fact that very large industrial organisations have exceptional power to influence politicians, trade union leaders and the Press, makes them a potential danger to democracy, and, although Great Britain is justly proud of the integrity of its political and industrial life, the possibilities of abuses in the region where they overlap are exceptional and cannot be disregarded.

Defects of Large Industrial Units

In Mr. Hopkinson's view, the dangerous influence of large industrial concerns is not offset by any contribution to the happiness and prosperity of the community. The existence of twenty separate firms engaged in a particular branch of industry means twenty sources of energy and enterprise: their amalgamation into one large unit eliminates nineteen of these sources. The only way in which a nation can preserve a standard of living higher than that of others is by continuing to produce goods of higher quality or goods which the others cannot produce at all: tariffs and embargoes are merely temporary expedients. It follows therefore that competition from countries with a lower standard of life can be met only by frequent changes in the nature, form or design of the goods produced; but it is just this condition which the large organisation finds most difficult to meet, owing to the inertia resulting from its very size. Again, very large firms have the power to stimulate markets by intensive advertising and hire-purchase schemes, but by thus compressing the purchasing power of a life-time into a few years, an unhealthy state of the market is induced, and a temporary advantage may be wiped out by a subsequent collapse. Finally, the estimate that 44 per cent of total factory production in Great Britain is in the hands of firms employing less than two hundred people indicates the important part which the small concerns play in industrial life: their contribution to the national exchequer is, no doubt, proportionately great.

Typhoon Season in the Far East

THE cyclone season of the northern tropics is this year being extended abnormally far into the autumn in the Far East as well as in the West Indies, for a typhoon visited the Loo-Choo Islands so late as November 14, and reached Tokyo late on the following night. The wind is reported to have blown with a speed of nearly a hundred miles an hour, and to have caused much material damage. The loss of life was fortunately small compared with that caused by the Cuban storm five days earlier. Although there seems to be no essential difference between the typhoon of the western part of the North Pacific and the West Indian hurricane, both being typical examples of the tropical cyclone, the typhoon season is not concentrated into a few summer and early autumn months to nearly the same extent as happens with the West Indian storms. There is, however, more similarity in the seasonal distribution of those storms that reach Japan. July, August and September are the dangerous months for Japan and the neighbouring seas; whereas the seas farther to the south are occasionally affected by a typhoon even in mid-winter and early spring, the occurrence of an intense developing typhoon near Japan so late as November is probably even rarer than a similar development in the West Indies. It is known that there is a connexion between the variations of the general circulation of the atmosphere and the regions of formation as well as the direction and speed of travel of tropical cyclones, but it is very doubtful whether the cause of the present abnormal prolongation of the cyclone season can be explained. It is points like this which may be cleared up when meteorologists possess a long series of daily synoptic charts for the northern hemisphere such as those now being prepared by the Deutsche Seewarte, Hamburg, described in NATURE of November 12, p. 748.

An Easily Portable Episcope

THE increasing appreciation of the value of episcopes in teaching has created a demand for an instrument, simple in construction, easy to handle, capable of being brought readily into the ordinary class room, and reasonably cheap. The Wigmore episcope which has been recently put on the market by Messrs. Newton and Co., 72, Wigmore Street, London, W.1, seems likely to meet this demand. It is light and, being provided with two carrying handles, can be easily carried from one room to another. It can be immediately installed and used in any room which has a projection screen and an electric lighting supply. In use, the episcope is simply placed upon the object to be shown on the screen; the externally mounted reversing mirror is tilted to bring the image to the required height; and the image is then brought into focus. Two 250-watt lamps are used for illuminating the field, which is 5 in. by 5 in.; but the map or drawing or book, a portion of which is to be projected, may be of any size. When the instrument is about 10 ft. from the screen, a well-illuminated picture 4 ft. square is

obtained with good definition over nearly the whole of the area. The working distance may be varied from 6 ft. to 24 ft., giving pictures from 2¼ ft. to 9 ft. square, with of course a diminution in intensity at the greater distances. The episcope, which costs £12 12*s*., complete with lamps, should prove particularly useful for illustrating lessons in classrooms or for demonstrations in small lecture theatres, where a very large picture is not required.

Cultivation of Living Tissue Cells

AT the Friday evening discourse at the Royal Institution on November 18, Dr. R. C. Canti exhibited films demonstrating the cultivation of living tissue cells. The films consist of moving photomicrographs of the living cells of animal tissues taken whilst they are growing outside the body. The individual pictures are taken at relatively long intervals but are projected on the screen at the usual speed of 16 pictures per second. This gives the effect of speeding up and approximately three weeks continuous photography is shortened into half an hour. The first film opened with the demonstration of a 'tissue culture'. This was followed by a picture of a fragment of periosteum of the chick embryo under low magnification which shows the outwandering of the cells from the central mass or explant. Higher magnification is then employed to demonstrate the structure of vegetative cells and the classical stages of cell division. The picture then changed from healthy to malignant tissue and showed the characteristic cells of a cancerous tumour of the rat known as Jensen's rat sarcoma. Dr. Canti's second reel was devoted to a demonstration of the contents of the cell by the method of dark-ground illumination, which reveals certain structures, for example, granules and mitochondria, invisible by the ordinary methods of trans-illumination. The third reel contained subjects of embryological interest, namely, the development of the rabbit ovum from the single cell up to the morula stage, the development of the young chick embryo from the primitive streak and the development of the bony femur from the cartilagenous rudiment in the six-day chick embryo. The apparatus for taking the photographs is a combination of the cinema camera, microscope and biological incubator, with a specially constructed automatic mechanism for making the exposures at the desired intervals.

Colour Films

THE paper read before the Royal Society of Arts on November 9 by Mr. T. Thorne Baker gave a useful account of new developments in colour cinematography. Compared with other inventions like radio-telephony, the aeroplane and sound films, the coming of photography in natural colours seems very slow. The coloured films which have been shown at many picture theatres during the last two or three years are nearly all two-colour pictures. The main drawback is that the colours obtained in these pictures are not absolutely natural. But now methods have been devised for obtaining three-colour pictures. These require for the development of a satisfactory studio technique an immense amount of further research. In the early days of the sound film, many thought that it would have a short life because the reproduction of both speech and music was so bad. Yet improvements have proceeded so rapidly that it is now so good that the demand for silent films has almost ceased. A similar series of events will probably take place in connexion with colour films. Most of the various attempts made to please the eye by two-colour processes have failed. It has taken years to put three-colour processes into practical form. But once the natural colour film has been seen by the public it seems that they will soon cease to think that it is a 'colour' picture and merely derive increased enjoyment from its naturalness. Similarly, the expert who is familiar with the latest developments of colour films feels when he looks at the ordinary film, notwithstanding the exquisite photography and the magnificent art which characterise modern productions, that a serious omission has been made.

The Past and the Future in Psychical Research

SIR OLIVER LODGE, in his presidential address to the Society for Psychical Research on the occasion of its jubilee in June, discussed the past and the future with special reference to the history of the Society. He recalled the events of the last fifty years and noted how the disapproval and hostility which was encountered in the early years of the Society's existence are gradually diminishing. The hostility, he maintained, was directed mainly by spiritualists, who disapproved of the cautious procedure of the Society's officers and of the criticism to which narratives were subjected before publication. Although this can scarcely be maintained at the present day, it is true that the founders of the Society, with the establishment of thought transference as their primary aim, were, in fact, endeavouring to apply the scientific method to their inquiries. In his insistence on this Sir Oliver is justified, in spite of such famous cases as that of Sir E. Hornby in 1884, where some attention to essential details would have absolved Mr. Frederic Myers and Mr. Edmund Gurney from charges of carelessness in the preparation of their data.

IN his further discussion of the past, Sir Oliver asked his audience to remember the pioneer work of Myers, who, although of literary and even perhaps mystical tendencies, nevertheless realised the importance of the scientific treatment of those problems which were his greatest interest. To convince the world of telepathy was the dominant note of the early years: to-day, Sir Oliver thinks, may be the time for the Society in its corporate capacity to declare its belief in the reality of the spiritual world and in its interaction with the physical one. It is on this note that the address ends, and it finally concludes by Sir Oliver again asserting his personal belief in the "cosmic and permanent" existence of the human spirit apart from the discarded material organism, with its memory, character and affections intact.

Deep Petroleum Wells

Mr. W. A. Sawdon contributes an interesting article to a recent issue of the *Oil Weekly* concerning the deepest oil wells yet drilled. The record which he gives proves conclusively the high state of efficiency to which petroleum engineering has attained in the last few years, and it would seem that, both from a technical and an economic point of view, the limit to the depth probed for oil has yet to be defined. The appearance of this article is timely owing to the fact that the deepest well drilled in the United States has just been completed in California, where a depth of 10,296 ft. has been reached. A feature of this well is that it was drilled with comparatively light equipment, contrary to the usual custom of involving extra heavy plant in order to achieve the great depths desired. This Californian well is not the deepest in the world, the record being held by a well drilled to 10,585 ft. in the State of Vera Cruz, Mexico. The first 10,000 ft. well to be drilled was, however, in California; this attained a depth of 10,054 ft. but, like the Mexican well, no production was obtained. Probably the greatest producing well is that which was completed in July last in California at a depth of 9,710 ft., from which an initial production of 5,050 barrels of oil a day, accompanied by 5,000,000 cub. ft. of gas, was obtained. All these wells were rotary drilled.

Two other interesting oil wells may be added to the list; one drilled by the percussion system (cable tool) in West Virginia to 9,104 ft., from which no production was obtained, the other, a Texas well, also drilled by the cable tool system to a depth of 8,900 ft. In the latter case a Diesel engine was employed as motive power instead of the more customary steam engine or electric motor as in the case of the other wells mentioned. Apart from technical development, in future the utility of the deep well will be governed entirely by economic circumstances, since any attempt to raise oil from a depth of two miles or more in the earth's crust must necessarily involve considerably greater expenditure in plant, equipment and running costs than has been the case in the past for shallower wells. There is little question that, assuming it is economically practicable, the petroleum engineering industry is capable of evolving both plant and operative system for attaining still greater depths, especially in cases where deeper-lying pay sands have to be tapped for the oil they contain. It is perhaps not difficult to visualise the day when over-production of oil will be a thing of the past and when reliance for the major part of the world's supply of crude petroleum will have to be placed on these very deep wells and on the revolutionised drilling technique which they imply.

Modern Methods in the Inland Telegraph Service

During the last two years, very rapid development has taken place in the inland telegraph service in Great Britain. Previously, a very exhaustive study had been made to find out the best methods of making the service more attractive to the public, more efficient as a means of communication, and less costly as regards the loss of State revenue. Instruments and machinery new to the service have been introduced. Teleprinters, typewriters, rectifiers, converters, thermionic valves and voice frequency signalling are the main features of the reorganised system. In a paper read to the Institution of Electrical Engineers on November 17, Mr. R. P. Smith described the new equipment in detail. A telegraph exchange service, 'the telex', has been made available to telephone subscribers, the necessary apparatus being installed on rental terms. The renters are able to receive and transmit printed communications in addition to the usual telephone facilities. They can also transmit messages to the Post Office, creating a new class of traffic designated 'Printergrams'—a word which we think not very happily chosen. We have now telegrams, phonograms and printergrams. At the present time, the supply of underground conductors is more than sufficient for the requirements of the public services. The vacant channels of communication are offered to the public, on rental terms, for the purpose of private wire circuits. The ascertained results of the reorganisation, which is still far from complete, show that the stability and accuracy of the service has been greatly increased. In addition, the latest figures show an improvement in the financial position. The changes also have increased the comfort and convenience of the army of workers who staff the telegraph instrument rooms.

Aerial Spotting of Fish Shoals

Since 1919, when the American Bureau of Fisheries first observed that fish shoals which could not be seen from the bridge of a ship were easily discernible from an aeroplane flying directly overhead, numerous attempts have been made to utilise aircraft for spotting shoals of fish. In Great Britain both the Ministry of Agriculture and Fisheries and the Scottish Fishery Board have made endeavours to locate herring shoals from the air but in both cases the experiments yielded no fruitful results. In the recently published report of the Danish Biological Station for 1932 interesting records of similar efforts to spot herring in Danish waters are given. Dr. H. Blegvad, director of the station, was in charge of the investigations and himself acted as observer. An important feature of the Danish experiments was that the Danish Broadcasting Corporation agreed to broadcast at once any information submitted to it from the exploring aeroplane. Unfortunately, only very few exceedingly small herring shoals were observed throughout the entire course of the investigations, which extended over forty flying hours. Their positions were immediately broadcast but the investigators were unable afterwards to obtain any information as to whether or not the broadcasts proved useful to the fishermen. Probably this entire lack of evidence is a very good indication of lack of positive results. The Danish investigators, therefore, like their British colleagues, have come to the

conclusion that, although in favourable conditions fish shoals in their waters may be spotted from the air, this method of locating fish is much too costly and uncertain to be of any practical value to the national fisheries.

The Future of Indian Agriculture

IN a survey and a forecast of the next twenty years in India (*Journal of the Royal Central Asian Society*, vol. 19, July 1932), Lieut.-Col. Sir Arnold Wilson makes a strong plea for the introduction of scientific method into public affairs. He predicts that in twenty years time the population of Asia will have increased by at least 20 per cent, and that in India alone the numbers may have grown to 427 millions. These figures mean that the great problem of the future will be that of food supply. Over the whole of Asia the predominant occupation is agriculture, while in India at least the cultivable area increases very slowly and seems to have reached the limit except for the redemption of barren areas by irrigation. Figures tend to show that in India the food yield has not kept pace with the growth of population, but that the gap has been partly filled by a decrease in the export of grain. Sir Arnold Wilson foresees the dwindling of this export trade and the growth of an import trade in wheat. To balance this, India will have to develop an export of other primary products, but the tendency will be to utilise these at home. An import of fertilisers will, however, be essential, for on the extended use of these in agriculture lies one of the few hopes for the avoidance of famine in the future and the maintenance of the present standard of living, low as it is.

Fenland Exploration in East Anglia

A COMMUNICATION from Mr. Miles C. Burkitt, which appears in *Man* for November, announces the inauguration of a committee for the exploration of the fens of East Anglia in connexion with the Cambridge Antiquarian Society and the Prehistoric Society of East Anglia. Recent archæological work in the area, notably a study of the prehistoric waterways by Major Fowler of Ely and of an early metal age site below peat by Mr. Grahame Clark, has served to demonstrate the importance of a region which can afford an unbroken sequence of deposits from quaternary to recent times. It is evident, however, that archæological investigation does not cover a sufficiently wide field for the complete study of the area, but needs supplementing by such studies, for example, as palæobotany and geology. It has, therefore, been decided, as already stated, to appoint a committee of experts to undertake systematic study in the various branches of scientific investigation between which co-operation is essential to a scheme of exploration. The Master of Downing, Prof. A. C. Seward, has consented to act as president and Major Fowler as vice-president of the Committee. Mr. Grahame Clark, Peterhouse, Cambridge, to whom communications relating to the work of the committee should be addressed, will act as secretary.

Rediscovery of an 'Extinct' Bird

RE-APPEARANCES of creatures regarded as extinct are occasionally reported but seldom proved. There can be no reasonable doubt, however, in the case of the black-capped petrel or 'diablotin' of Dominica, *Pterodroma hæsitata*. For many years this bird has been regarded as extinct, the last recorded capture having been made in 1871, but recently reports have become current that odd examples have been seen. The present position is summed up in a short article in the *Journal of the Society for the Preservation of the Fauna of the Empire* (Sept. 1932, p. 17). In 1900 Richmond stated that he had seen three, more have been observed in Haiti, and on May 2, 1932, Mary Rose (of Roseau, Dominica) invited a naturalist to examine a strange bird found lying helpless at her door after a stormy night. The naturalists who saw it (it died on May 26) agree that it was a 'diablotin'; and apparently the bird, although extremely rare, still breeds in the mountain fastnesses of Dominica. It is gratifying to find that steps were at once taken to ensure so far as possible the safety of the remnant, and on July 1 a special legislative order was issued granting the petrel full protection.

Magnetic Declination in the United States

THE U.S. Coast and Geodetic Survey makes magnetic observations at a set of repeat stations every five years, and publishes the results at similar intervals, in the form of tables of secular variation, and of charts showing the results of the original complete survey, made mainly between 1900 and 1910, brought up to date. A recent pamphlet by D. L. Hazard ("Magnetic Declination in the United States, 1930", U.S. Dept. of Commerce, Coast and Geodetic Survey, Washington; Serial 540, 1932; pp. 40, 10 cents) does this for the magnetic declination; the chart gives isogonic lines at 1° intervals, and lines of equal annual change at 1′ intervals. It contains much tabular matter and information of value to land surveyors, and is issued at a very low price.

Meldola Medal

THE Meldola medal (the gift of the Society of Maccabæans) is awarded annually to the chemist whose published chemical work shows the most promise and is brought to the notice of the administrators during the year ending December 31 prior to the award. The recipient must be a British subject not more than thirty years of age at the time of the completion of the work. The medal may not be awarded more than once to the same person. In awarding the medal for 1932, the adjudicators will, unless exceptional circumstances arise, give special consideration to work in physical or inorganic chemistry. The next award will be made in January 1933. The Council of the Institute of Chemistry would therefore be glad to have its attention directed, before December 31, to work of the character indicated. Communications should be addressed to the Registrar of the Institute, 30 Russell Square, London, W.C.1.

Announcements

THE Christmas Lectures at the Royal Institution are to be given by Prof. A. O. Rankine, professor of physics in the Imperial College of Science and Technology, on December 27, 29, 31, January 3, 5 and 7 at 3 o'clock. Prof. Rankine has chosen "The Round of the Waters" as the title of this, the "one hundred and seventh course of six lectures adapted to a juvenile auditory".

IT is announced by Science Service, Washington, D.C., that the John Fritz Gold Medal for 1932 of the American engineering institutions has been awarded to Daniel C. Jackling. Mr. Jackling, who has done much work in mining engineering and metallurgy, especially in the development of low-grade ores, was awarded the medal for "notable industrial achievement in initiating mass production of copper from low-grade ores, through application of engineering principles".

THE annual Congress of the Royal Institute of Public Health will be held at Eastbourne on May 30–June 4, under the presidency of the Right Hon. Viscount Leverhulme. The Congress will be divided into five sections: State medicine and industrial hygiene; women and children and the public health; tuberculosis; pathology, bacteriology, biochemistry and veterinary medicine; climatology and hydrology. Further information can be obtained from the Secretary, 23 Queen Square, London, W.C.1.

THE trustees of the Rockefeller Foundation have made a further grant of £5,000 towards the research funds of the National Institute of Industrial Psychology to be expended in the years 1933–1936. This is the fourth grant made by these trustees to the Institute. These gifts have enabled the Institute, under the personal direction of Dr. C. S. Myers, its principal, to conduct an extensive series of researches upon subjects having a direct bearing on industrial and occupational life.

AT the annual general meeting of the Philosophical Society of the University of Durham the following officers were elected for the session 1932–33: *President:* Prof. R. A. Sampson; *Vice-Presidents:* Profs. J. W. H. Harrison, P. J. Heawood, G. R. Goldsbrough, G. R. Clemo, G. H. Hickling, and J. Irvine Masson; *Hon. General Secretary:* Mr. W. M. Madgin; *Hon. Treasurer:* Mr. J. W. Bullerwell; *Editor:* Prof. G. W. Todd; and *Hon. Librarian:* Dr. F. Bradshaw.

DR. J. Florian, Brno, Czechoslovakia, writes to point out that in his article on "The Early History of the Cell Theory" in NATURE of October 22 the first sentence of the second paragraph should read:—"Studnička came to the conclusion that the small granules ('globules') of 1/300 mm. in diameter, which H. Milne Edwards (1823) found in all the tissues he examined, are of varied origin and in great part mere artefacts." By a misunderstanding, for which the correspondent who sent us the article is responsible, the sentence read: "In 1823 H. Milne Edwards came to the conclusion that the small granules ('globules') of 1/300 mm. in diameter," etc. Dr. Florian saw a proof but unfortunately overlooked the alteration which had been made in the sentence.

IT is announced in *Science* of October 28, that the ninety-first meeting of the American Association for the Advancement of Science will be held at Atlantic City on December 27–31, under the presidency of Dr. John J. Abel. The opening general address will be delivered by the retiring president, Dr. Franz Boas. The first Maiben lecture, a new lecture established in memory of H. Maiben, will be given by Dr. H. N. Russell on "The Constitution of the Stars". The general headquarters of the Association will be Chalfonte-Haddon Hall, which will also house the members representing general science. On the other hand, members of the various sections of the Association will stay in definite hotels allocated to each section. So far as is possible, each section will hold its meetings at the hotel thus assigned to it.

ARRANGEMENTS have been made for Dr. Davidson Black of the Peiping Union Medical College, China, who will arrive in England early in December, to give a course of lectures in advanced anatomy in the University of London. The course, consisting of two lectures on *Sinanthropus*, will be given at University College, Gower Street, London, W.C.1. The first lecture will be delivered on Friday, December 9, at 5.30 P.M., and the second on Monday, December 12, at the same time. In addition to an account of the morphological characters of *Sinanthropus*, the lectures will include a historical statement and a description of the environment, physical and biotic, and the cultural horizon. Admission to all the lectures will be free and without ticket.

IN a review in NATURE of November 5, p. 682, reference is made to the transparent cellulose film "Cellophane". We have been asked to point out that this name is the registered trade mark used by The Cellophane Co., Ltd., and its associated companies to designate their product.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in chemistry (subsidiary botany) at the Woolwich Polytechnic, Woolwich, S.E.18—The Secretary (Nov. 29). A county librarian for the Buckinghamshire County Education Committee—The Secretary for Education, County Offices, Aylesbury (Nov. 29). A temporary junior chemist at an Admiralty inspection establishment—The Secretary of the Admiralty (C.E. Branch), London, S.W.1 (Dec. 10). An assistant librarian at the University of Glasgow—The Librarian (Dec. 15). A field geologist for economic investigation (not oil) in Iraq—The Crown Agents for the Colonies, 4, Millbank, Westminster, S.W.1 (Dec. 17).

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Quantitative Estimates of Sensory Events

DR. ALLAN FERGUSON's article on Weber's law in NATURE of September 3 (p. 334) is to be welcomed as an eminently sane statement on a subject about which much nonsense has been talked. Fechner's work has been too much attacked by verbal discussion on the nature of measurement which Dr. Ferguson rightly criticises.

This speculative discussion has directed the attention of Fechner's critics from a serious mathematical blunder. Fechner integrated for the whole value of R values from zero upwards (assuming, therefore, that Weber's law held over this whole range), but after integration, he made a substitution which assumes the existence of an absolute threshold of stimulus below which there is no sensation (which is plainly inconsistent with the truth of Weber's law at low R values). This leads to the absurdity of negative sensation values when the stimulus is below threshold value, and the crowning absurdity of an infinite negative sensation for zero stimulus. This defect, however, is not fatal to Fechner's work and may be avoided by the method adopted by Dr. Ferguson of integrating only over the range of R values in which Weber's law, in fact, holds.

A further difficulty, however, arises from the fact that it is not certain that there is any range of stimulus intensities over which Weber's law is valid. The method of experimenting which has commonly been used on the authority of Fechner (that is, asking the subject for a judgment as to which of two stimuli is greater) does not give very self-consistent results, so no very close approximation to any law can be expected. Using Weber's original kind of stimulus—pressure—and a simpler experimental method giving greater self-consistency, I have found no indication of a tendency for $\Delta R/R$ to be constant. Any relationship is complicated by the fact that different kinds of sense organs are stimulated at different intensities of pressure, but an overlapping system of curves approximating to Houstoun's law seems a more probable explanation of the results obtained. This does not seem to be a mere result of a change in experimental method, since the old results given in the textbooks seem, on critical examination, to give no real support to Weber's law. Results commonly stated to be 'near enough to Weber's law' (such as Max Wien's on sound intensities), when reduced to a graph, are not very much like a straight line parallel to the base. Many such 'confirmations' of Weber's law prove on examination to be, in Mark Twain's words, a little straighter than a corkscrew but not so straight as a rainbow.

Dr. Ferguson is undoubtedly right in suggesting that the real problem of Fechner's work is unaffected by whether we start from Weber's law or some more complex relationship between R and S. The assumption in the passage from a law connecting differential thresholds with absolute values of the stimulus to a formula of the general form $S = f(R)$ or $S_1 - S_2 = f(R_1, R_2)$, (Fechner's implied assumption that just perceptible increments of sensation are equal sensation increments) may be regarded as a convention of measurement comparable with Fahrenheit's convention that he would take as equal temperature steps those that made equal volume increases in his mercury. If this convention gives us a system of numerical coefficients consistent with the experimental facts of judgments of relative supraliminal sensation differences (as apparently it does), it matters little whether or not we are to be allowed to call this process 'measurement' or by some other name.

It must be agreed that the conception of the sense interval is a mere evasion of the difficulties of the sensation. Several years ago, I described experiments at a British Association meeting which showed that the absolute sense interval involves precisely the same difficulties as the absolute sensation magnitude.

The greatest harm to the development of experimental psychology has come from Weber's law and not from Fechner's work. Fechner has contributed to this harm by focusing attention on Weber's law. The harm has been two-fold. First, experimenters have for half a century been occupied with trying to confirm or refute Weber's law, instead of with the real problem of trying to establish the more complex relationship which really holds between sensation and stimulus intensity. Much worse is the fact that they have been almost entirely occupied with those conditions of simplified perception in which alone sensation intensity is simply a function of stimulus intensity, and have neglected the much more important and interesting problems of perception which arise under less artificial conditions in which the perceptual experience is a function of the total experimental setting.

ROBERT H. THOULESS.

Dept. of Psychology,
University, Glasgow.
Sept. 7.

DR. FERGUSON's discussion in NATURE of September 3 (p. 334) would have been briefer and possibly clearer if he had based it upon the general principles of measurement. These have been recently formulated by several independent writers; it is true they are not generally known, but they never will be if everyone refuses to refer to them. The chief of them may be stated briefly thus:—There are two distinct processes of measurement; one of these ('fundamental') is based on the recognition of a relation of equality and a process of addition, obeying certain laws; the other ('derived') consists in the assignment of a numeral representing the constant of a numerical law. Let us apply these to sensations.

In so far as the law

$$\delta R = kR$$

is valid, k is a true *derived* magnitude, exactly co-ordinate with density or viscosity. But that does not afford the smallest presumption that there is a *fundamental* magnitude S, between values of which the k's are differences; it is that presumption that has misled the followers of Fechner. It is certainly improbable that a quantitative science of sensation can be established unless a *fundamental* magnitude characteristic of it can be found; but the way to find such a magnitude is to seek for a process of addition, not to juggle mathematically with numerical laws.

The success of the search depends largely on what is meant by a sensation. Some psychologists hold that two sensations of the same kind cannot be experienced simultaneously. If they are right (and the question is not entirely one of words), sensations cannot possibly be measurable fundamentally; for it is quite certain that there is no process of addition whereby two non-simultaneous sensations can be combined so as to be equivalent to a single instantaneous sensation. If, on the other hand, we experience two simultaneous sensations when exposed to two stimuli, sensations can be combined and it is a question of experimental fact whether such combination satisfies the laws of addition. The most likely of these to fail is the associative law that, if a is equivalent to a' and b to b', then a combined with b is equivalent to a' combined with b'. For the sensation of brightness, this law (and certain others) are true within limits; that is why heterochromatic photometry is possible. Those who dismiss it as irrelevant on the ground that it measures stimuli and not sensations often fail to observe that heterochromatic brightness differs from homochromatic brightness and other typically physical magnitudes, because it cannot be measured by 'physical' methods, independent of any *specified* form of sensation; its measurement is inseparable from a sensation of a particular kind.

The law need not, however, be true for sensations of other kinds. It is almost certainly untrue for painfulness; and I doubt whether it is generally true for loudness. The loudness of added sounds is probably affected by their concordance or dissonance. But the experiments that might decide the matter definitely do not seem to have been made; until they are made, it is waste of time to discuss whether sensations are measurable.

Some people seem to believe that, though sensations are not measurable by either of the two physical processes, they may be measurable by some third process inapplicable to the magnitudes of physics. They should remember that physicists will not accept any process as measurement, unless it is based upon laws the validity of which is appreciable equally by all observers who are not so abnormal as to fail to appreciate their meaning.

NORMAN R. CAMPBELL.

THE two letters printed above emphasise the necessity for further discussion of the problem—a discussion which may very well be applied both to the vast mass of existing experimental data, and to the conditions under which fresh data may be sought.

The reason for the line of development adopted in my article will be apparent to anyone acquainted with the literature of the subject; and, as was pointed out clearly enough in the text, one of the primary matters to be considered in a future discussion is that of the application to the problem of the fundamental principles of measurement, the importance of which Dr. Campbell so rightly stresses. Anything that Dr. Campbell has to say on such a subject will be heard with respect; nonetheless, readers of his incisive letter should remember that a vigorous statement is not necessarily a final statement of the truth.

Lubricating Oils and Cancer

THE letter from J. B. Speakman and N. H. Chamberlain,[1] suggesting that "the incidence of dermatitis and tumours may be caused by the difficulty of removing mineral oil from the skin", is supported by the fact that unsaturated mineral oils on exposure to light and air form compounds which are not emulsified by soaps, and which form coatings on wool fibres that are only removed with difficulty by solvents, and not at all by soaps. This insoluble layer is a possible source of irritation. Crude shale oils give a considerable amount of such insoluble compounds.[2]

Also, in the course of research work by the second of the undersigned, on emulsification problems in scouring of wool and wool fabrics, it has been noted that the ionisation process developed by E. V. Hayes-Gratze in co-operation with the Wool Industries Research Association, applied to a variety of oils, especially vegetable oils, gives striking results.

It gives products of greatly lowered surface tension, and highly water-emulsifiable nature, providing a means of wool oiling whereby not only are "oxidised oil" defects, to which commercial lanoline is subject, eliminated, but subsequent scouring is accomplished with the greatest ease.

In addition, hospital tests have shown that ionised oils possess remarkable curative properties in treatment of obstinate cases of dermatitis and ringworm, so that it may be inferred that their presence would tend to prevent skin infection, apart from facilitating removal of oil contamination.

A Continuous Spectrum of Pure Argon

IN the course of investigations that have been made at the Electrical Laboratory, Oxford, of the electrical properties of argon, it was found that when the gas is obtained in a high degree of purity several phenomena occur, in the appearance of the discharge and in the spectrum of the light emitted, which do not appear to have been noticed before. The argon was carefully purified by a method which will be described in another paper. It was examined spectroscopically at pressures from 1 millimetre to 150 millimetres and no lines due to impurities were detected in the range of wave-lengths from λ 2000 A. to λ 7000 A.

It was found that when an electrodeless discharge was excited in argon by continuous oscillations of about 100 metres wave-length in a tube 1·7 cm. in diameter, the discharge assumes two forms which depend upon the pressure of the gas and the intensity of the current. When the current in the tube is large, the discharge is a striated column, the striations consisting of globules (the size of which decreases as the pressure is increased) which lie along the axis of the tube between the electrodes; a form of the discharge which has already been described in a previous paper.[1] A recent photograph of this type of discharge in pure argon at about 40 mm. pressure is shown in Fig. 1. When the current in the tube is decreased, the striations disappear and the distribution of light in the tube takes the form shown in Fig. 2. In the striated column the colour

is purple and in the uniform column the colour is white. In a tube of 1·7 cm. diameter, at pressures less than 8 mm., it was not found possible to obtain the uniform column, and the discharge was striated for the smallest currents which could be maintained

FIG. 1.

in the tube. Similar results were obtained in wider tubes, both of pyrex and of quartz.

The spectra emitted by the luminous column in the two types of discharge exhibit interesting variations as the pressure is increased. When the pressure is less than about 6 mm., only the line spectrum

FIG. 2.

of argon is excited. As the pressure is increased, a continuous background appears which increases in intensity with the pressure, while the line spectrum becomes less intense. At the highest pressures (80–150 mm.) the line spectrum is completely absent from the uniform column with the exception of the

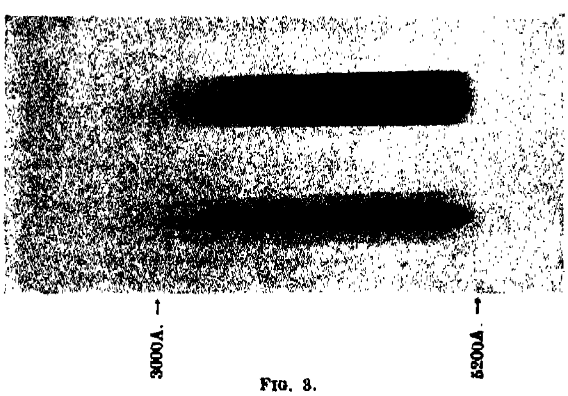

FIG. 3.

argon red line at λ 6965 A. The spectrum appears quite continuous from 6000 A. to about 2250 A., which is as far as can be measured with the spectrograph used. At the highest pressures in the striated column the continuous background appears as strongly as in the uniform column, but in addition the stronger lines of the argon red spectrum are visible above the continuous background.

Photographs of the spectrum of the striated and continuous discharges obtained in pyrex tubes containing argon at a pressure of 150 mm. are shown in Fig. 3. These were taken on Ilford Zenith 650 plates. Photographs will be published later of the spectra obtained with quartz tubes and panchromatic plates. These plates show the continuous spectrum sharply cut off at about λ 6000 A. and extending as far into the ultra-violet as can be measured with a quartz spectrograph in air, while the red line at λ 6965 A. appears prominently.

A very interesting feature of these investigations is that they show that it is possible to obtain a continuous spectrum in a gas discharge, over a wide range of wave-lengths, where the characteristic lines of the gas are absent.

Continuous Spectrum of Sodium

I HAVE investigated the intensity distribution of the continuous spectrum of sodium, which is generally considered to be the halo of the D lines, and also of the relative intensity to the systems of discrete bands, under various conditions of excitation, and the main results obtained are here described.

The continuous spectrum begins to enhance when the pressure is increased to 1–2 mm., and as the pressure of vapour is increased more and more, without altering the temperature, the intensity of the discrete bands as well as that of the continuous spectrum are both increased considerably, the increasing rate of the former being greater than that of the latter.

Where the temperature of the vapour varies under a constant pressure, it is known that the more intensely the discrete bands are emitted, compared with the continuous spectrum, the lower the temperature of the vapour, but as the temperature of the vapour becomes higher, the case is reversed.

The intensity distribution of the continuous spectrum is nearly symmetrical on both sides of the wave-lengths and is at a remarkable maximum at the D lines, and the rise of temperature, without altering the pressure, or increase of pressure, the temperature being kept constant, causes the relative or absolute enhancement and, therefore, the (apparent) broadening of the spectrum. In the region of the shorter wave-lengths, its intensity decreases moderately at about 5600 A. and fades abruptly with a comparatively sharp edge at about 5500 A., and as we proceed farther towards the side of the shorter wave-lengths, the intensity of the weak continuous spectrum gradually decreases and terminates more or less abruptly at about 4550 A., while, on the side of the longer wave-lengths, its intensity is gradually and uniformly decreased.

The rotation structure is always sharply defined without showing any appreciable broadening of the band-lines as the result of the increase of pressure, and also of the rise of the temperature, until the condition (very high temperature) is arrived at where the discrete bands, and therefore each separate band-

line, ultimately disappear. It is proved that there is no direct connexion between the structure of the discrete bands and the continuous spectrum.

The continuous spectrum mentioned above may certainly be explained by the emission of the excited ^3P atoms during their collisions with other normal atoms (quasi-molecules). It seems that the emission of the main part of the strong continuous spectrum in the back-ground of the red band system is closely connected with the transitions $^1\Sigma_u^+ \to {}^1\Sigma_g^+$ of the quasi-molecules. Similarly, the continuous spectrum

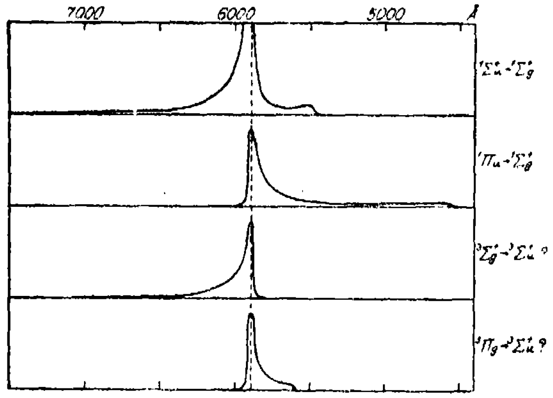

FIG. 1.

in the back-ground of the green band system seems to have an intimate connexion with the latter band system ($^1\pi_u \to {}^1\Sigma_g^+$). Besides, there is also possible the emission of a continuous spectrum due to the transitions $^3\Sigma_g^+ \to {}^3\Sigma_u^+$ and $^3\pi_g \to {}^3\Sigma_u^+$ of the quasi-molecules on the side of the longer wave-lengths of the D lines, or in the vicinity of them (Fig. 1).

The main part of the continuous spectrum emitted from the sodium arc, or from the sodium flame, when the density of sodium vapour is fairly high, has the same distribution of intensity as that obtained in this experiment.

Similar results are obtained in the case of potassium.

Discontinuous Distribution in Plants

IN NATURE of July 9, p. 58, I gave an account of a genus of bees (*Hesperapis*) which was found to exist in dry regions of the south-west United States, and again in the dry parts of South Africa. I have just received from the Missouri Botanical Garden a very thorough revision of the genus *Menodora*, by Julian A. Steyermark. This is a genus of oleaceous plants, found in dry or semi-desert regions, in south-west North America, a large area in Central and southern South America, and a few forms in the Transvaal and adjacent parts of South Africa. Thus except for the South American area, the distribution nearly corresponds with that of *Hesperapis*.

One of the South African forms, certainly native and frequently collected in the Transvaal, has been supposed to be identical with *Menodora heterophylla*, which is abundant in Texas, and occurs in the Mexican States of Tamaulipas and Nuevo Leon. Mr. Steyermark points out that in spite of the great resemblance, the South African plant differs in a number of respects, so that he calls it variety *australis*. Evidently it should rank as a separate species, *Menodora australis*, as it cannot be supposed to have any direct genetic connexion with the North American plant. Mr. Steyermark himself calls it "a very striking instance, seemingly, of parallel development". On p. 109, however, he writes: "*M. heterophylla*, occurs with its variety in two widely separated continents, namely, North America and Africa. Since this distribution may be explained by the supposition of the existence of a land-bridge forming a ready means of dispersal for species between the continents, it may be supposed that *M. heterophylla* extended from North America to South Africa over the postulated lost continent, Gondwana, before the end of the Cretaceous."

This seems to me to be wholly fanciful, and had there been any such connexion, is it likely that this species of plants has remained unchanged since the Cretaceous, or that a few forms crossed over, leaving the mass of the fauna and flora behind? There is no reason to doubt that the genera *Menodora* and *Hesperapis* are of great antiquity, and presumably spread to their now remote outposts by way of Asia, but very similar species have evolved independently under similar conditions. Unfortunately xerophytic conditions are not favourable for the preservation of fossil plants and insects, so that we get very little evidence from the rocks concerning the past plant or invertebrate life of dry regions. We do, however, find in the Miocene deposit at Florissant, Colorado, fossil Proteaceæ, a family of plants now especially characteristic of South Africa and Australia, and a species of Nemopteridæ, curious insects with long slender hind wings, known from southern South America and dry regions of the Old World, but to-day wholly lacking in North America.

The distribution and origin of desert life may well attract all students interested in the wider aspects of biology. After visiting desert and semi-desert regions in many parts of the world, one is struck by the extraordinary character of the responses to the environment, producing similar and highly characteristic organisms, often of quite different origin. Judging by the completeness of the adaptations, and the great number of peculiar types, it seems that the South African desert area has some claim to be considered the oldest of them all.

Protective Properties of Colloids and their Behaviour in the Electrolytic Deposition of Metals

PREVIOUS observations made by me[1] on the mechanical stress in cathode plates during electrolysis of copper sulphate, showed that the effect of gelatin in the solutions is marked at very low concentrations (0·5–1 mgm. per litre). The state of the solution is also of great importance, the stress varying considerably with the age of the solution. This makes it possible to follow the evolution of a solution as a function of time by the electrochemical method.

I have continued my experiments with other colloids: serum albumin, gum arabic, gum tragacanth, and dextrin, in concentrations varying from 1 to 500 mgm. per litre. The results show a very

pronounced parallelism between the protective action as measured by the gold number of the colloid substance and its action on the electrolytic deposit. Highly protective substances (gelatin and serum albumin) modify considerably the stress in the copper, whereas the less protective (gum arabic and gum tragacanth) have a much smaller effect. The dextrin with its very high gold number has no effect in the limits of the concentrations examined.

These results show that the effect produced by the colloids on the electrolytic copper deposit must be attributed mainly to phenomena similar to those manifested in protective actions, that is, they have to be brought back finally to adsorption.

Application of the Gold-Beater's Skin Test to Some Synthetic Tannins

IN several communications[1] we have shown that the generally accepted reactions for the tannins are quite unreliable, with the result that the abovenamed test was evolved.[2] The gold-beater's skin test demonstrates the *tanning* properties of a substance, and is given *only* by true tannins. Its application to the following synthetic tannins, prepared according to Emil Fischer,[3] digalloylglycol, trigalloyl-glycerin, tetragalloyl-erythrol and hexagalloyl-mannitol, shows them to possess no tanning properties whatever. These observations thus extend my objections,[4] since further emphasised by Tschitschibabin,[5] to Fischer's galloyl-glucose formula of gallotannin.

Inheritance of Acquired Characters

THE response evoked by my letter in NATURE of October 1 calls for a reply. Dr. R. A. Fisher, in his interesting communication,[1] points out that before my conclusion is accepted there are one or two preliminary points to be considered. His suggestion that the somewhat retarded ages of fatherhood of the upper and middle classes would alone explain the greater age of paternity cannot, I think, be accepted: the frequency curve would surely be displaced so as to be substantially parallel to the normal curve, but this is not the observed fact. Again, Dr. Fisher states that the comparison would be more valid if based upon birth order: I venture to suggest that this is quite a different proposition, although ability is undoubtedly correlated with birth order. The suggestion that the differences may be due to environmental modifications is a more plausible one but it cannot, I think, be sustained: a father seventy years of age is not likely either to survive to influence his child during the critical years of adolescence or to provide a substantially better environment than a father fifty years of age.

If my thesis is true it is important eugenically, since there emerges the possibility of materially improving a stock in one generation. In this connexion the tradition that Isaac was born when Abraham was an hundred years old and Sarah ninety is interesting, seeing that from him sprang the whole Jewish race. The story in *Genesis* is very circumstantial and emphasises that both parents were old and well stricken in age. It is commonly held, I believe, that such progeny is necessarily degenerate.

Ecology of Man's Ancestors

IN his recent book "The Causes of Evolution" (p. 10) Prof. J. B. S. Haldane makes the following incidental remark: "Thus that common enemy of man, the bed-bug belongs to a family whose members are mostly parasitic on bats. Dr. Buxton has, I think, suggested that it is a relic of the association of our palæolithic ancestors with bats in caves." It is, indeed, interesting to note that a number of other animals associated with man and his immediate environment belong to the ecological group of rock and cave communities. The members of the family Cimicidæ to which the bed-bug belongs are predaceous (not parasitic in the strict sense of the word) not only on man and bats, but also on pigeons and house-martins, and the original habitat of these birds, as well as of swallows, is amongst cliffs and in caves. The predaceous bug *Reduvius personatus*, often preying on the bed-bug, is found only in houses and sheds, but other species of the genus occur amongst stones, in rock crevices, etc., in the Mediterranean region. The same largely applies to the house-cricket and to the myriapod, *Scutigera*. The typical cave bugs belonging to the subfamily *Emesinæ* are represented in the animal community grouped around man by several species of the genus *Ploiaria* (for example, *P. domestica*). The geckos are typical rock animals but they are just as commonly found on the walls of houses.

All these facts lend strong support to the hypothesis that man originally belonged to the community of cave-inhabiting animals rather than of forest-dwellers such as the anthropoid apes. It would be of great interest to make a thorough analysis of the animals commensal with man in various countries with regard to their systematic, zoogeographical and ecological relations, since this may throw some light on the early history of mankind. So far as we know, this much discussed problem has not yet been attacked from the ecological point of view.

Implements from the Raised Beach at Slindon Park, Sussex

WITH the help of a grant from the Percy Sladen Memorial Fund, I have recently examined the raised beach at Slindon Park, situated between Arundel and Chichester.

The section shows some 8 ft. of raised beach, consisting mainly of flint cobbles. Its surface lies

at about 135 ft. above O.D., and is covered by a deposit of Coombe Rock, varying from 6 in. to 9 ft. deep. Three main facts result from my investigation:

(1) The raised beach contains Chellean hand-axes and large thick flakes, both much rolled.
(2) At the top of the beach occur Acheulean ovates.
(3) Next comes a flake industry, which preceded the deposition of the Coombe Rock.

(1) The large flakes from the beach closely resemble in form and colour those found in the Cannon shot gravels of Norfolk. There are traces of striation. Some are reminiscent of Clacton types.

(2) From the top of the beach come several Acheulean ovates. Some are moderately rolled and battered; others are unabraded. We are probably dealing with a storm beach, which was occasionally subjected to the action of the sea. The subsidence involved is about 120-125 ft.

(3) The lowest part of the Coombe Rock contains a floor yielding remains of a flake industry. There are Levallois flakes with facetted platforms, and flakes struck from unprepared cores. The industry includes rough hand-axes, both ovate in shape, and with squared corners, also choppers and large points, 'Abri Audi' in form.

From the 80-90 ft. raised beach south-west of Slindon Park, I have obtained several rolled flakes of Cannon shot gravel type.

I suggest that much of the beach belongs to the same interglacial period as the Cannon shot gravels. Its latest phase may be contemporary with (a) gravel deposits at Corfe Mullen near Wimborne in the Hampshire basin, where the surface of the gravel is about 135 ft. above the river; (b) the Dartford Heath gravel in the lower Thames valley, where the top of the gravel reaches 137 ft. above O.D. Both these sites contain late Acheulean ovates.

The Coombe Rock at Slindon readily falls into line with a similar deposit which buried the early Mousterian workshop at Northfleet, and with the Upper Chalky Boulder Clay of East Anglia which succeeded early Mousterian cultures at Hoxne and Foxhall Road, Ipswich.

Mr. J. Reid Moir has kindly examined my material, and is in agreement with my general conclusions. A full report will be published in due course.

Angle of Elevation of Short Wave Rays

AN important problem in short wave propagation from both the purely scientific and the commercial aspect concerns the angle of elevation of the path of the ray both at the transmitting and receiving end.

During the past year the Radio Section of the Post Office Engineering Department has been investigating this problem. At Rugby Radio Station, energised aerials consisting of one or more tiers of horizontal radiators have been raised in stages from the ground and the resulting field has been measured near New York by the staff of the American Telephone and Telegraph Co., and the Bell Telephone Laboratories, who have closely collaborated in the tests. By plotting a series of curves giving the relative field strength of the rays projected at various angles of elevation as the aerials were raised and comparing with the received fields, it has been possible to ascertain the direction taken by the ray at the transmitting end. The details of the tests will be published later. In the meantime it is relevant to record that the usually accepted theory that for long distance transmission almost grazing angle to the earth gives the best distant field is inaccurate in the case of the Rugby-New York circuit. The investigation shows that during the past year the best angle of projection of waves traversing an all light path has varied only $\pm 2°$ or $3°$ from $10°$ to the horizontal.

Aerials giving rise to beams of varying concentration having their maximum radiation at angles of elevation changing from 5° to 10° have shown in all cases that the average field as measured at the receiving end has corresponded approximately to that portion of the energy radiated along a direction having an angle of elevation of 10°. Field-strength measurements made in Berlin and Teneriffe by the courtesy of Herr Baumler of the Reichspostzentralamt, and Mr. W. H. Warren of the Compania Telefonica National des Espana, confirm that there is a definite angle of projection of energy along which attenuation is a minimum.

This angle is not necessarily the lowest to give a minimum number of reflections from the F layer associated with the name of Prof. E. V. Appleton.

Dr. William Garnett

THE obituary notice of Dr. Garnett in NATURE of November 12 omits to mention his long connexion with the Royal Commission for the Exhibition of 1851; and as Dr. Garnett was justly proud of his membership of this body, perhaps a supplementary note may be of interest. The facts are these: Dr. Garnett was an original member of Lord Playfair's committee which devised and introduced the Commissioners' scheme of research scholarships, a scheme which has done so much for the improvement of scientific education both at home and overseas, and has also contributed in no small measure to the advancement of science. From 1890 until a few months ago, Dr. Garnett served without intermission as a member of the Science Scholarships Committee of the Royal Commission, and his recent resignation from that body, prompted by increasing deafness which latterly prevented him from following discussions at meetings, deprived the Committee of its senior member and its oldest friend; and now his death removes the last link with that eminent body of men of science to whose wisdom and foresight higher education in Great Britain owes so much. I am privileged to know that, on his relinquishing his active participation in the affairs of the Royal Commission, Dr. Garnett received from H.M. the King a most gracious message of appreciation of the valuable services which he had rendered to the Commission for more than forty years. I believe that readers of NATURE will be glad to have their attention directed to this further aspect of his long and useful life.

Research Items

Peking Man.—The skeletal remains other than the skull parts of Peking man, of which the announcement of the discovery was purposely delayed, have now been described by Dr. Davidson Black (*Bull. Geol. Soc. China*, 11, No. 4) The greater part of a left semi-lunar bone (os lunatum) was found by Dr. Bohler in material from Locus *B* of the Choukoutien cave. It is undoubtedly to be referred to the genus *Sinanthropus*. It differs in no important respect from that of modern man and confirms the inference from the stone implements, crude though they are, that the hands of Peking man were essentially like our own. In a culture stratum yielding quartz implements, from which came two adult jaw fragments and a parietal fragment of *Sinanthropus*, was also found a fragment of clavicle. It is the greater part of the shaft of a well-formed left clavicle lacking the sternal epiphyseal articular portion and the acromial fourth of the bone. It is moderately mineralised and a dark reddish-brown. The individual from whom it was derived was probably adult. The probable length, 15 cm., is about the average length of an adult modern North China male clavicle. A number of anomalous terminal phalanges have also been recovered, which could not well have belonged to any animal other than a hominid form. Expert opinion confirms this. In the first specimen recovered, the roughened area of the tuberositas unguicularis encroaches on the dorsal surface of the bone more widely, while ventrally it is much less developed, than in any known hominid. If it is the terminal phalanx of the hallux of *Sinanthropus*, it would seem probable that the morphology of the feet of this form and that of modern man differed much more widely from one another than that of their hands.

Pueblos on Zuñi Reservation.—The excavation of an ancient Pueblo site on the Zuñi Reservation, New Mexico, is described by Mr. F. H. H. Roberts, jr., in Bull. 111, of the Bureau of American Ethnology. When the site was excavated in 1930 it was found that the settlement consisted of three communal dwellings and two great kivas or ceremonial chambers. On account of the latter feature the site is to be known as the "Village of the Great Kivas". Two dwellings and one kiva were completely excavated. The larger dwelling consisted of three small ceremonial chambers, a great kiva and sixty-four rooms, of which four had constituted a second story. In addition there were four detached subterranean ceremonial chambers in front of the east end. The building had not been erected as one unit, but there had been several periods of constructive activity. The original structure was a rectangular block of thirteen rooms and two small ceremonial chambers. Up to the close of at least the first two of the periods of activity, the house type was predominantly that of the Chaco canyon, that is, of the northern Pueblo type. The character and size of later additions suggest an infiltration of other peoples, probably from the south. The kivas associated with the house are of two types. The smaller house contained twenty rooms. Originally a fairly small dwelling, it had been enlarged at various times. The material was more carefully worked than in house A. It had no kiva, another indication of its probably southern origin. Sixty burials were uncovered; but the remains were in poor condition. The skulls showed pronounced occipital flattening and a large proportion of decayed teeth, the latter feature probably being due to a deficiency in diet. The village seems to have had a population of about 100. It belongs to Pueblo III and dates from about A.D. 1000–1030, the period of Pueblo expansion.

Tuberculosis in Children.—Our knowledge of the pathology and bacteriology of tuberculosis in children has been extended by the work of Dr. J. W. S. Blacklock, detailed in a report issued by the Medical Research Council (Special Report Series, No. 172. London: H.M. Stationery Office. 3*s*. net). It supplies additional evidence of the paths by which infection comes, based upon a study of the primary sites in which the disease developed in 283 children found at autopsy to be tuberculous. The ages of the subjects were from a few hours up to thirteen years. Of these 283 children with tuberculous damage, more than 90 per cent died as the result of the infection; the site of the primary damage was most frequently in the chest (173 cases, or 61 per cent). Evidence was sought of the pathway of infection to the lung and lymphatic glands. For this purpose, a characteristic lung lesion described by Parrot half a century ago and recognised as marking the primary site of infection was sought for; this was found in 148 of the 173 cases, and the tubercle bacillus was isolated in most of them and examined as to its type—human or bovine. Wherever the primary lung lesion of Parrot was found, only bacilli of human type were obtained either from the lesion itself or from the glands in direct relation to it. Dr. Blacklock concludes from all the evidence that the pathway of infection in these cases has been by the air—all these children were infected through the air-passages by bacilli derived from other human beings. Investigations were also made on primary abdominal and surgical tuberculosis, and upon the significance of tuberculin reactions.

Clyde Bivalves.—Mr. A. C. Stephen (*J. Marine Biol. Ass. United Kingdom*, vol. 17, No. 1, 1932) has continued his investigations on the intertidal lamellibranchs of the Clyde, chiefly at Millport, and adds to his list certain forms living below low water mark, using the Robertson bucket dredge put through a 2 mm. sieve, with a check sample through a 1 mm. sieve. Four species are dealt with in the present paper—*Tellina tenuis*, *T. fabula*, *Abra alba* and *Cardium edule*. All these are important economically as fish food, *Cardium edule* (the common cockle) also as human food. *Tellina tenuis* extends to about 2½ fathoms but its growth is slower beyond low water mark than in any other part of its range, and the present results show that it is best adapted to life in the intertidal area. *T. fabula* extends from about low water mark to a depth of 10 fathoms. It grows rapidly, attaining a length of 4 mm. at the end of the first year, 8 mm. in the second and 10 mm. at the end of the third year. For both species the years 1926 and 1930 were exceptionally good for spat survival. It is found that after the disappearance or great thinning of any population, it is apparently renewed from spat, and the author is of the opinion that the clearing of the ground of adults as a result of high mortality after spawning or after unusual frost is the important factor for the survival of spat. Thus on the shore at the head of Loch Fyne, all the

cockles above low water mark were killed off by the severe winter of 1928–29, most of the present population being derived from the 1929 spat. The rate of growth in the cockle is greater at low water mark than farther up the beach. If it grows slowly in the first year it tends to lag behind always. Shells of the same length from higher levels are lighter than those from lower down.

Cultivation of *Catenaria*.—*Catenaria anguillulæ*, a chytridiacean fungus, has been found parasitic in the eggs of the liver-fluke of sheep (*Fasciola hepatica*), in the eggs of other helminthes and in small aquatic organisms. Evidence points to the tap-water in London and in Dublin as the source of infection of the eggs in the laboratory experiments. The cultivation of this *Catenaria* is recorded by J. B. Butler and A. Humphries (*Sci. Proc. Roy. Dublin Soc.*, vol. 20, No. 25, 1932) using various artificial media containing an aqueous extract of the eggs of the fluke with or without agar, and/or, egg albumen. In culture the development of mycelium was much more extensive than when the fungus was growing as a parasite. In one instance a single thallus produced more than twenty hyphal strands each bearing three to four sporangia. In another example more than 700 sporangia were present in a single outgrowth, possibly involving only one thallus. The more extensive development of the mycelium in artificial media supports the view that *Catenaria anguillulæ* is a form reduced through the influence of parasitism. Zoospores from the sporangia germinated on an artificial medium and produced a thallus, zoosporangia and zoospores. The variability of shape of the sporangia in culture and other points in the morphology are noted.

Digestive Enzymes in the Animal Organism.—As is well known, the digestive enzymes secreted in the animal organism pass into the urine, their presence therein furnishing a means of measuring the intensity of their formation and the activity of the digestive processes. In vol. 34 of the *Rendiconti della Reale Accademia delle Scienze dell' Istituto di Bologna* dated 1930 but only now just received, Prof. Pietro Albertoni describes experiments in which taka-diastase was injected into the blood of the dog. After the injection—into the jugular vein—the submaxillary saliva was examined and was found to be, as normally, devoid of diastatic properties. Stimulation of the chorda of the tympanum rendered the saliva denser but did not cause it to become diastatic. Hence the enzyme does not pass into the saliva, although it retains its physiological action since, injected into the blood, it determines mobilisation of the glycogen, producing hyperglucæmia. Thus, there is no question of a circulation of the digestive enzymes, which are absorbed but do not re-appear in the various secretions, and in all cases represent a specific product of the various glandular apparatus.

A New Method in Plant Taxonomy.—Kiichi Ohki appears to have given the 'spodogram' method of distinguishing species a very thorough examination in connexion with his studies of the Japanese Bambusaceæ, and does not appear dissatisfied with the method. The spodogram is obtained by taking a small piece of the leaf from the middle region and incinerating it carefully using a special apparatus first suggested by Werner (*Biologia Generalis*, 4, 1928). The ash when cool is mounted on a slide, with xylol and Canada balsam. In this way the outlines in particular of the epidermal cells are retained because of the silica contained in their walls. At first sight it would appear more reasonable, if such microscopic characters are to be used in taxonomy, to examine the full leaf tissue without resort to incineration, when the same characters together with others will be available for study, but the method of incineration certainly reduces the salient microscopic characters to a limited group, recognisable after incineration, which may be more simply treated in systematic study. Ohki's paper will be found in the *Journal of the Faculty of Science* (Tokyo, Section 3, Botany vol. 4, Part I).

British Basidiomycetæ.—Mr. Carleton Rea has re-published Appendix 2 to his book "British Basidiomycetæ" (*Trans. Brit. Mycol. Soc.*, vol. 17, Parts 1 and 2, pp. 35–50, 1932). The newly-described species belong to the genera *Pluteus*, *Lepiota*, *Psalliota*, *Amanita*, *Stropharia*, *Cortinarius*, *Inocybe*, *Tricholoma*, *Entoloma*, *Clitocybe*, *Hygrophorus*, *Flammula*, *Collybia*, *Leptonia*, *Mycena*, *Russula* and others. Many are uncommon or rare, but a few are common. Four new species and one new variety are described. These are *Psaliota floccosa* Rea, *P. impudica* Rea, *Leptonia acuta* Rea, *Clavaria griseola* Rea and *P. campestris* var. *squamulosa* Rea. Diagnoses of the five are given in Latin and English and they are illustrated upon an excellent coloured plate. Mr. Rea's "British Basidiomycetæ" is the most complete work which has appeared on the subject and it is most useful that the author should keep it up-to-date by the periodical descriptions of new species and varieties.

Heat Excluding Roofs.—In a paper on "Radiant Heat" read before the Institution of Heating and Ventilating Engineers on November 2, Mr. A. F. Dufton summarised the results which have been obtained at the Building Research Station on the relative merits of various forms of thin roofs as excluders of heat due to sunshine from the buildings they cover. Most roofing materials absorb about three-fourths of the sunlight that falls on them; for example, red tiles 67 per cent, blue slates 85 per cent, red asbestos tiles 74 per cent, old roofing lead 77 per cent, bituminised felt 89 per cent, galvanised iron when new 65 per cent, and when old and dirty 91 per cent. Whitewashing the upper surface of any one of these reduces the absorption considerably, for example, that of the dirty iron to 26 per cent. A glass roof under which the temperature was 188° F. when the temperature outside was 70° F. in the shade, when given two coats of whitewash on its top surface showed a temperature underneath of only 103° F. Mr. Dufton has not been able to detect that the rays from an incandescent electric light relieve the congestion of the nose produced by the radiation from an electric fire, although Sir Leonard Hill stated some time ago (*Times*, August 13) that they have this property.

Cosmic Radiation.—The issue of the *Physikalische Zeitschrift* for September 1 contains a valuable summary of our present knowledge of cosmic radiation with a long list of references, by Prof. Hoffmann of Halle. Systematic observations are now being made at Abisko, Königsberg, Potsdam, Innsbruck, Amsterdam, Dublin, Bandoeng and Cape Town, and each month new facts are discovered and new questions raised. After describing the electrometer, tube counter and Wilson chamber methods of

measurement, the author gives the principal results obtained. Curves of increase of the radiation with height in the atmosphere and of decrease with depth below the surface of water are given. With increase of barometric pressure the radiation decreases. It appears to come equally from all parts of the sky. The harder part of the radiation appears not to vary in amount with time but the softer part appears to be influenced by meteorological conditions in the atmosphere. The absorption of the radiation as it passes through matter is complicated by the production of corpuscular radiation. The question of variation of the radiation with position on the earth's surface is still unsettled, and much of the theory as to the origin of the radiation is speculative. (See also NATURE, 130, 570, Oct. 15, 1932.)

The Green Salt of Magnus.—The green compound of bivalent platinum obtained by Magnus in 1828 by the action of ammonia on platinous chloride is usually considered to be a complex salt $[Pt(NH_3)_4]$ $[Pt\,Cl_4]$, and a detailed X-ray examination published by Cox, Pinkard, Wardlaw and Preston (*J. Chem. Soc.*, Oct.) shows that this is the case, the four ammonia and chloride groups being arranged in a square about the platinum atom. A pink form also obtained is generally a different substance, namely, Cleve's salt, $[Pt(NH_3)_3Cl]_2$ $[PtCl_4]$, although in exceptional cases a pink orthorhombic form which is the true analogue of Magnus's salt is formed. It is suggested that, since the true pink salt of Magnus and Cleve's salt are convertible into the green salt, the transformation of Cleve's salt to Magnus's salt may take place by interchange of co-ordinated groups between anions and cations, and the ions of the Magnus salt would temporarily have a non-planar configuration. The pink salt may be this unstable form intermediate between the other two. The planar arrangement in the green salt of Magnus is analogous to that in K_2PtCl_4 and $[Pt(NH_3)_4]$ Cl_2, but in the latter the ammonia groups are rotating, whereas in Magnus's salt the evidence shows that they are not. This is no doubt due to the lower symmetry in the structure of the latter.

Astronomical Topics

Astronomical Notes for December.—Venus is still observable as a morning star, rising about $2\frac{1}{2}$ hours before sunrise, with five-sixths of its disc illuminated. Mercury is about 7° east of Venus in the latter half of December. Mars and Jupiter are observable after midnight; they are only 4° apart at the end of the month. This will be the last opposition of Jupiter in north declination for some years, so advantage should be taken of it. Mars is $1\frac{1}{2}$° north of Neptune on December 5. Uranus is still well placed for observation, in Pisces. It is stationary on December 28.

The winter solstice occurs at 1 A.M. on December 22.

The following are the times of the disappearances of stars occulted by the moon (as seen from London). ι Aquarii, December 3, 6^h21^m P.M.; μ Arietis, December 9, 11^h7^m P.M.; ρ Leonis, December 19, 0^h29^m A.M. (bright limb); the last star re-appears at the dark limb at 1^h25^m A.M., angle 331°.

A meteor radiant in the north of Gemini is sometimes active in the first half of December. Denning gave December 11 and 12 as the dates of maximum, but owing to moonlight, there would be a better chance some days earlier.

The most conveniently observable minima of Algol occur about 9 P.M. on December 16, and 6 P.M. on December 19.

The Leonid Meteors.—The weather in the London district was very unfavourable for observation on all the nights when meteors were expected. The only success reported in England is that of Mr. J. P. M. Prentice, the director of the meteor section of the British Astronomical Association, at Stowmarket; he recorded 20 Leonids between 5 and 6 A.M. on November 16; one of them was of magnitude − 3. The moon was so near that faint meteors would have been missed; moreover, there was a slight haze. Still, it is clear that if the earth had entered the dense part of the stream the number seen would have been much larger; if a great shower was seen anywhere, it was probably in the region of the Pacific Ocean, from which reports might be slow in reaching us. There is still a prospect of a rich shower next November; the great shower of 1866 was ten months after the perihelion passage of Tempel's comet. The moon will then be new.

Accelerations of Sun, Moon and Planets.—Dr. J. K. Fotheringham contributes a paper on this subject to the *Observatory* for November. He notes that it is now established that the solar and planetary fluctuations are correlated with the whole lunar fluctuation, not merely with the part that remains when the great empirical lunar term is excluded. The establishment of this fact facilitates the determination both of the individual fluctuations and of the secular accelerations, which cannot be deduced from modern observations until the fluctuations are known. The establishment of these preliminaries makes Mercury, on account of its rapid angular motion, the most suitable body for determining the solar and planetary accelerations. This and other lines of evidence lead to secular accelerations of 1·4″ and 4·8″ for the sun and moon respectively, the latter being in addition to 6·0″ for the La Place term (revised). The accelerations are proportional to the mean motions, except in the case of the moon. The value for the sun is confirmed, within narrow limits, by the independent researches of Prof. de Sitter, Herr C. Schoch, and Dr. Fotheringham. Thus results that were formerly the subject of much controversy may now be considered as fairly well established.

The ancient eclipses of sun and moon give the excess of the lunar acceleration over that of the sun, so that when either of these is found the other is deducible. Dr. Fotheringham announced at the meeting of the Royal Astronomical Society on November 11 that a portion of a tablet from Nineveh, which has been in the British Museum for many years, has now been deciphered with the aid of hints supplied by him. It proves to be a table indicating the manner in which the hours of day and night were reckoned. The day and night were each separately divided into six double hours, which consequently were not equal for day and night, but varied with the seasons. This clue will make it possible to improve the time determinations for the recorded eclipses of sun and moon, which may lead to a small revision of the values of the accelerations.

Imperial Cancer Research Fund*

THE tenth scientific report of the Imperial Cancer Research Fund is a substantial and profusely illustrated account of such of the researches carried out under the guidance of Dr. J. A. Murray as have not been published in the journals.

Five of the papers now published deal with the action of radium on tumours. The most important is by Dr. W. Cramer, who points out that a dose of radium radiation quite insufficient to kill cancer cells outside the body will often lead to the complete disappearance of growths to which it is applied *in situ* in the body. If a tumour irradiated in the body is after a few hours removed to another site in the same animal, it grows progressively. Hence, though radium has certainly some directly destructive effect on cancer cells, its main efficacy in curing tumours must be due to its action on the tissues of the host and so altering the surroundings of the tumour that it cannot survive. There is, as Miss Pullinger has also recently shown in human material, much damage to the blood vessels and also a great accumulation of leucocytes and other phagocytic cells, and it seems as if radium acts largely by encouraging the usually futile resistance which the tissues present to a growing tumour.

Dr. Cramer also shows that radium tends to inhibit or delay the carcinogenic action of tar. Dr. R. J. Ludford has analysed in detail the cytological effects of radium on a number of tumours, while Mr. Crabtree gives the results of an elaborate investigation of the influence of radium on the carbohydrate metabolism studied by Warburg's method. The results are negative in the sense that no difference was found between normal and malignant tissues, and glycolysis, specially characteristic of cancers, was in fact more affected than respiration. He has also examined the action of radium on the succinoxidase ferment of muscle

The other four papers, by Drs. Ludford and Foulds, are concerned with the reaction of tumours to vital staining with colloidal acid dyes. The chief results are that malignant cells do not segregate the dyes into their cytoplasm as normal cells do, and that the histiocyte series of phagocytic cells (which have a particularly intimate relation to vital stains) plays a substantial part in the resistance of the body to cancer, the details of which are at present not understood.

The thirtieth annual report of the Fund has also recently been issued. Among domestic affairs we notice with much regret that Sir Frederic Hallett has been compelled through ill-health to resign the post of secretary which he has occupied with such success since the foundation of the Fund thirty years ago. Appropriately enough, he is to be succeeded by Mrs. Harvey, daughter of the late Dr. E. F. Bashford, the first scientific director, who laid down the scope and objects of the Fund's investigations so well. The report also contains a very valuable summary by Mr. H. G. Crabtree of the present state of knowledge about Warburg's claim that the essential metabolism of the cancer cell differs from that of normal tissues. The claim has, on the whole, failed to stand the test of the voluminous investigations which it excited, but it has led to much interesting work and those who desire to know the situation as it stands at present cannot do better than consult Mr. Crabtree's account.

Electrical Units

SEVERAL of the many interesting papers presented to Section 2 of the International Congress of Electricity held in Paris last summer dealt with electrical units. Thirty years ago the general opinion prevailed that the realisation of the 'international' electrical units was much easier than that of the so-called 'absolute' units based on the c.g.s. system, but experience acquired in the last twenty years has considerably modified this view. H. L. Curtis, in Paper No. 4, discusses the various methods in use for the measurement of current in 'absolute' c.g.s. units, and urges the furtherance of investigations. The determination of the ampere in the c.g.s. system of units can at present be carried out with an accuracy probably higher than that attainable in the determination of the 'international' ampere by the deposition of silver.

E. Giebe, in Paper No. 3, writing on the determination of the ohm in absolute units, discusses four methods, of which two are in use at the National Physical Laboratory, one at the Physikalisch-Technische Reichsanstalt, and one at the U.S. Bureau of Standards; he concludes that "the accuracies of realisation of the absolute unit of resistance and of the mercury ohm are about equal," and adds: "the international mercury unit in use up to the present has decreased in importance, and could be discarded. This view was adopted in 1929 by the Comité International des Poids et Mesures, who on the recommendation of a committee of experts, decided to replace the international unit hitherto employed by the absolute unit, for technical as well as scientific purposes, and to accomplish the change as soon as a few more absolute measurements have confirmed our already accurate knowledge of the ratio of the two units."

Turning to the more technical papers, one by E. H. Rayner (No. 16) describes the electrostatic voltmeters and ammeters in common use at the National Physical Laboratory. The voltmeters, of the Kelvin multicellular type and all of the same range, are characterised by the lightness of the moving system, which weighs only 2·6 gm., although it comprises ten needles, a mirror and the damping device. Bifilar suspension secures great constancy of the zero point. The 130 volt range of the instrument is increased to about 40 kilovolts by resistance dividers, and to several hundred kilovolts by capacity dividers. The wattmeters are likewise made in one size only, have four quadrants and a single needle. "The three-electrode instruments used for measuring power and cognate magnitudes have been developed into wattmeters of a sensitivity and adaptability hitherto unattained by any other process. . . . A single instrument of each kind (voltmeter and wattmeter) with auxiliary apparatus consisting mostly of precision resistances, renders possible the measurement of almost all

electric magnitudes at power frequencies, with a range of sensitivities and an accuracy which it would be very difficult to obtain by other means."

N. E. Dorsey summarises and discusses, in a paper of general interest (No. 10), the results of the most important determinations of the velocity of light, of the ratio of the electromagnetic to the electrostatic unit of electricity, and of the velocity of propagation of Hertzian waves. He concludes that experiment confirms modern electromagnetic theory in regarding the results as being determinations by three different methods of one and the same quantity, and gives 299,792 kilometres per second as the most probable value. Dorsey directs attention to the apparently systematic decrease in the values obtained for the velocity of light during the last fifty years, but does not agree with Gheury de Bray that the fact indicates an actual decrease in the value of *C*, for, quoting from comments on the subject which appeared in these columns (NATURE, 120, 594, Oct. 22, 1927): "An absolute change in the velocity of light . . . could scarcely obtain acceptance unless supported by much more decisive observational material."

Engineering Methods in Optical Manufacture

MR. WILLIAM TAYLOR'S valuable presidential address on October 28 to the Institution of Mechanical Engineers gave a very illuminating résumé of the modern methods of photographic lens manufacture in use in the famous Leicester factory of Messrs. Taylor, Taylor and Hobson, Ltd., and of a number of original methods which are the fruit of his own genius as an engineer. Amongst these innovations may be mentioned the tubular cutter for lens blanks, the annular carborundum wheel for roughing, improved fine-grinding and polishing machinery with an automatic supply of rouge and water, and special machines for edging. The description of these, published in the *Proceedings* of the Institution, will well repay reading by all interested in methods of optical manufacture or allied processes.

It is at first sight surprising, as the address hints, to find very primitive methods still surviving in some optical workshops, and this in spite of all that modern engineering and mass production methods can achieve. It is no slight on Mr. Taylor's originality to remind ourselves that Robert Hooke suggested, nearly three hundred years ago in the preface to his "Micrographia", the use of the grinding wheel on an inclined adjustable axis for producing curves of any required radius, for there is a long step between the geometry of the method and its successful application in practice. It has to be recognised, too, that operations and machines which can be worked successfully in a large factory for more or less continuous production are beyond the scope of a smaller concern where the optical work, though important, does not justify the installation of any but essential machinery.

The logic of the mass production thesis is the concentration of production in a few centres; the problem which it brings is the fair distribution of the wealth created, both in the form of goods and leisure. The mainspring of the whole movement in mechanisation is, as Mr. Taylor implies, the ever-present urge to overcome physical limitations of all kinds. In itself, this is one of the most excellent of human aspirations, and the spirited defence of mechanisation which forms the closing part of the address is unanswerable, provided that mankind is educated up to the duties which its privileges involve. But since our ethical and political development is so slow, we may sometimes tremble lest over-quick rationalisation should produce a condition beyond our power to control.

Apart from considerations of this kind, it is unlikely that optical manufacture has yet reached a finally definitive stage; we may speculate, however, as to whether future advances will consist in a slow progress in matters of detail, or whether some leading invention will render possible the production at will of non-spherical surfaces of prescribed form and optical accuracy. This latter is, indeed, no new problem. Food for thought will be found in the theoretical work on the subject dating from the time of Descartes, and the practical experiments of Fraunhofer, Bessemer, Parsons, and others. Optical accuracy has not been attained, but our command over physical processes is growing, and grinding is not the only method of producing surfaces of required form.

Mr. Taylor has shown us that progress can still be made by courageous attack, and we should ask for nothing better than to venture forward.

L. C. M.

New Gaseous Lamp

ON November 15 at a special meeting of the Illuminating Engineering Society held at the Wembley Laboratories of the General Electric Company, Ltd., Mr. C. C. Paterson read a paper on luminous discharge tube lighting. He pointed out that the current through the discharge tubes does not follow Ohm's law. It varies in a complicated way with the pressure of the gas inside the tube, the apparent resistance diminishing as the current increases.

The new discharge tubes were suggested by Pirani in Berlin and by the General Electric Company of America. They make use of the experimental fact that if the cathode is heated to a temperature at which it will emit electrons freely, the voltage fall at the cathode will be greatly reduced and so large currents can be passed without serious sputtering taking place. The electrodes of these tubes or 'gaseous lamps' consist of alkaline earth oxides which can be heated electrically like small filaments. With the use of these electrodes the cathode fall is only about twenty-five volts. The current therefore can be thirty or even a hundred times as large as that obtainable with ordinary cold cathodes, being only limited by the heat developed by the discharge. The pressure of operation is so small that it can be obtained from any ordinary electric supply. The gas or vapour inside the gaseous lamp must emit a suitable spectrum and it must not decompose under the action of the discharge.

There are several other conditions the tube must fulfil. It has been found that a white light can be obtained from a neon tube provided a definite small

quantity of mercury vapour is present. It is not possible to mix a number of gases and vapours in one tube as each gas requires a definite voltage to stimulate it. It is not possible, for example, to harness a mixture of mercury and sodium vapour and neon gas in the same tube and so combine them to obtain a suitable radiation.

The fire-fly restricts its radiation to the visible spectrum only, whilst in the ordinary lamp a large proportion is emitted in the infra-red. The former is consequently an extremely efficient light source. If all the energy supplied to a discharge tube were emitted at a wave-length of 5,550 A., corresponding to the peak of the luminosity curve of the eye, the luminous efficiency would be about 670 lumens per watt. Compare this with the 12 lumens per watt of a 100 watt incandescent lamp. In practice it is now possible to make 100 watt sodium lamps with an efficiency of 70 lumens per watt. If the internal losses in the tube were negligible, theory shows that the efficiency would be 360 lumens per watt. Pirani has obtained this efficiency in the laboratory but it is impossible, as yet at least, to obtain it in a commercial lamp.

The development of gaseous lamps has been taking place rapidly during the last year. By placing neon and mercury tubes in parabolic reflectors, very efficient lamps suitable for flood-lighting are obtained. A 400 watt lamp is being developed at Wembley which seems very suitable for lighting streets and important thoroughfares. The street outside the Wembley Laboratories was shown illuminated in this way with very satisfactory results. Some people might find difficulty in distinguishing a 1*d*. stamp from a 1½*d*. stamp by the light from these lamps. Sodium lamps were developed first by Pirani in Berlin. There is a section of road admirably lighted by these lamps in Holland and another in Zurich. A similar lamp developed at Wembley is being tried for lighting stretches of arterial and country roads where the lack of good colour discrimination is of little importance.

Many avenues of research in connexion with gaseous lamps are still unexplored. It seems certain that their colour will soon be improved and that their efficiency will be very appreciably increased.

Industrial Research and National Problems

SIR FRANK SMITH, secretary of the Department of Scientific and Industrial Research, delivered the Norman Lockyer lecture of the British Science Guild on November 22, taking as his subject "Industrial Research and the Nation's Balance Sheet". Sir Arnold Wilson was in the chair.

Sir Frank Smith urged that the active prosecution of industrial research is essential for improving Great Britain's national balance sheet, which in the past ten months has shown an *apparent* adverse balance of some £263,749,000. To go on paying its way, it is necessary for British manufactured products upon which, together with its invisible exports, depends its ability to pay for imports, to continue to be as good or better than those of its competitors, while at the same time prices must not be higher. To this end, increased mechanisation and increased use of knowledge are necessary and "it is essential that the floodgates of international trade should be opened and that some measure of stability and freedom should be given to currency systems". These topics are discussed whenever men meet, but not so often do we hear of the necessity of financing industrial research, without which we shall fail to sell many of our products. "If a country had to choose between new knowledge and gold . . . the wise choice would undoubtedly be new knowledge for with it the gold can be obtained whereas without it the gold will be lost."

One hundred years ago there was no such thing as organised industrial research, and progress depended either on isolated research of men of genius or on accidental and unrelated observations. Later, in the nineteenth century, scientific men at the universities were occasionally asked to solve some of the problems of industry, but with the growth of the electrical, chemical and metallurgical industries, which depend on science for their very life, our industrial research laboratories came into being. "These laboratories aim at preventing industrial waste, at the standardisation of processes of manufacture and of the products, at lessening the costs of production and at the production of new types of goods. Their work does not replace the pure research work carried out at the Universities. It is supplementary to it. The outstanding characteristic of pure research is that it aims at increasing knowledge irrespective of application and it cannot be organised in the same way as industrial research. As Sir Joseph J. Thomson has said, 'Great ideas in science are as wayward as the fancies of a poet, and they cannot be controlled and organised.' "

Though industrial research has made great headway in Great Britain and the greatest and most successful undertakings have research laboratories of their own, this country is in many respects still doing less than some of its competitors; "there is with many industries far too much timidity and hesitation, and these must be overcome if this country is to retain much of our old-time supremacy in manufacture and export more manufactured goods."

Referring to the scheme for co-operative industrial research associations initiated by the Department of Scientific and Industrial Research in 1918, Sir Frank stated that there are now more than five thousand firms connected with the twenty research associations which have been set up. These firms have contributed about one and three-quarter millions to the cost of the work carried out. An investigation carried out by H.M. Chief Inspector of Factories covering nearly 128,000 factories employing about five million workers showed that less than five hundred of these factories employed more than one thousand workers each, while 117,147 factories employed less than one hundred workers each. It is well to urge that "industrial firms should build research laboratories, but it is obvious that not one of these 117,147 firms can take an effective part in industrial research as an isolated unit. . . . Co-operative research is the only solution to the problem of applying science to small units."

Sir Frank Smith then proceeded to consider the relations between research and the national balance sheet, in the case of Great Britain's largest import, food-stuffs; its greatest material asset, buildings; and its greatest natural asset, coal. He pointed out that the scientific study of refrigerating devices, which not so long ago were, like the photoelectric cell, mere toys of the laboratory, together with the

investigation of the biological problems involved in the transport and storage of foodstuffs, are doing much to help the national balance sheet by reducing imports through preventing waste.

In industrial processes care is taken to keep wear and tear of plant at a minimum and to design plant which is not likely to be obsolete, in such a way that replacement costs are comparatively small. The nation's most valuable plant is in the form of buildings, the value of which is estimated by Sir Frank at £4,500,000,000. Here science is helping by better planning and construction and by showing the builder how to choose his materials to greater advantage.

In the case of coal there are four ways in which research can help the trade balance: first by mechanising still further the hewing of coal and increasing the use of machinery in mines, thereby increasing our production power; secondly, by discovering means of obtaining more units of useful power from the fuel burnt; thirdly, by better marketing made possible by the application of the results of a scientific and comprehensive survey of our coal resources now being carried out; and fourthly, by the discovery of new and better methods for converting coal into powder, liquid and gaseous forms and the full utilisation of these forms.

University and Educational Intelligence

BRISTOL.—The annual Henry Herbert Wills memorial lecture will be delivered on December 15 at 5.15 P.M. in the Wills Laboratory by Lord Rutherford. The title of the lecture will be "Atomic Transformations". Admission will be by ticket obtainable from the Secretary.

LEEDS.—The honorary distinction of emeritus professor has been conferred upon Profs. F. W. Eurich, C. M. Gillespie, and R. S. Seton, who recently retired from the chairs of forensic medicine, philosophy and agriculture respectively.

LONDON.—The following degrees have recently been awarded: D.Sc. degree in biochemistry to Prof. E. C. Dodds (professor of biochemistry at Middlesex Hospital Medical School) for published papers on hormones, supported by 42 other papers and 3 books; D.Sc. degree in botany to Helen Kemp Archbold (Imperial College—Royal College of Science and Bedford College) for a thesis entitled "Ripening Processes in the Apple and the Relation of the Time of Gathering to the Chemical Changes in Cold Storage" (*Ann. Bot.*, July, 1932); D.Sc. degree in chemistry to Mr. J. R. I. Hepburn (East London College and Northern Polytechnic) for five published papers on "The Vapour Pressure of Water over Aqueous Solutions of Inorganic Electrolytes", and Ramsinha Thakur (Imperial College—Royal College of Science) for a thesis entitled "Three-Carbon Tautomerism in Dicyclic Systems"; D.Sc. degree in physics to Mr. J. H. Jones (King's College) for a thesis entitled "The Diffraction of Elastic Waves at the Boundaries of a Solid Layer Embedded in a Medium Possessing Lower Elastic Wave Velocities" (*Proc. Roy. Soc.*, A., 1932); D.Sc. in chemistry to Mr. B. S. Evans for twelve independent published works in inorganic analytical chemistry, together with four conjoint subsidiary contributions.

A STATEMENT for the academic year 1931–32 has been issued by the Rhodes Trust, Seymour House, Waterloo Place, London, S.W.1, from which it appears that, during the year, 71 Rhodes scholars took up their scholarships at the University of Oxford for the first time. The total number of scholars in residence during the year was 196, comprising 103 from the British Empire, 89 from the United States and 4 from Germany. Classifying the scholars by the subjects read, there are 42 taking natural science and medicine, 7 mathematics and 2 forestry.

THE annual conference of the Geographical Association will be held at the London School of Economics, Houghton Street, Aldwych, W.C.2, on January 4–6, and at the Imperial Institute, South Kensington, on January 7. The presidential address will be delivered by Dr. H. R. Mill on "An Approach to Geography" on January 4. Among the lectures to be given at the Conference are: Mr. J. M. Scott: "The British Arctic Air Route Expedition, 1930–31"; Mr. G. Huxley: "The Work of the Empire Marketing Board"; the Right Hon. Lord Meston: "Contrasts in the Ganges Basin"; Prof. Kenneth Mason: "The Exploration of the Himalaya"; Prof. R. G. Stapledon: "Climate and the Improvement of Hill Grazings"; and Sir John Russell: "Modern Changes in the Sources of our Food Supplies". Further information can be obtained from the Clerk, Geographical Association, Municipal High School of Commerce, Princess Street, Manchester.

Calendar of Geographical Exploration

Nov. 28, 1605.—Discovery of Australia

Willem Janszoon of Amsterdam sailed in the *Duifken* from Bantam, Java, hoping to discover more about New Guinea. He reached the coast of New Guinea in lat. 5° S. and followed the shore round Prince Frederick Henry Island to the beginning of Torres Strait. Thence he steered south and traced the eastern shores of the Gulf of Carpentaria to 13° 45′ S. Janszoon thought the coast was part of New Guinea. Attempts to open up trade with the sparse groups of natives failed, nine of the crew being murdered by them. The Spanish, under Torres, in the 1605–7 expedition discovered the true nature of Torres Strait, but not until 1762 was this realised, for Spain was then entering on a period of decadence and the results of the voyage were overlooked. Whatever vague reports of a southern land may have existed before the voyage of the *Duifken*, Janszoon's exploration of the Gulf of Carpentaria forms the first record of the discovery of Australia.

Dec. 3, 1738.—La Vérendrye and his Sons

Pierre Gaultier de Varennes, Sieur de la Vérendrye, reached a Mandan village, after having for the first time in this latitude crossed long. 100° W. La Vérendrye began his famous career of exploration in Canada in 1726, constantly aiming at reaching the Pacific Ocean. In this he failed, but on his last journey (1738) he accomplished more than half the distance between Montreal and the Pacific. To him and to his sons is due the pioneer opening of the beginning of that route west of Winnipeg along which the Canadian Pacific Railway afterwards went. The La Vérendryes discovered Lake Manitoba, explored the Saskatchewan to the junction of the two main branches and established many forts. La Vérendrye's eldest son was killed in 1738 by Indians, but the other two in 1742 set out with Mandan guides and reached a mountain range with snow-clad peaks, probably the Rookies, though possibly the Bighorn Mountains.

Societies and Academies

LONDON

Royal Society, Nov. 17.—A. Michels and C. Michels: The influence of pressure on the dielectric constant of carbon dioxide up to 1,000 atmospheres between 25° C. and 150° C. The method used was in principle the heterodyne beat—one with a frequency of 508 kilocycles. By special arrangements it was possible to keep the beat note constant for long periods within 1 frequency per second. The dielectric constant varied between 1·0009 and 1·73. The accuracy obtained was ± 0·00035. The Clausius-Mosotti expression has been calculated below 100° C., and for pressures above 100 atm., as only in this region are there sufficient compressibility data. Owing to the accuracy of these latter, the accuracy of the Clausius-Mosotti expression is limited to one half per cent. The values found do not change with temperature by an amount greater than this figure, but show a tendency to decrease with increasing pressure.—**E. N. da C. Andrade and B. Chalmers:** The resistivity of polycrystalline wires in relation to plastic deformation and the mechanism of plastic flow. The specific resistance of metals which crystallise in the cubic system is unaffected by plastic flow, but for those which crystallise with a unique axis of symmetry it changes during the intermediate of the stages. For some metals the change is an increase, for others a decrease, the difference of sign being explicable in terms of the orientation of the slip planes in relation to the crystalline structure of the metal, supposing that there is rotation of the crystallites during the stage of the flow in question. At liquid air temperature the sign of the change of resistance of cadmium reverses, an effect which can be traced to the heavy twinning which takes place under stress at this temperature, as against distortion by glide at higher temperatures. A general result is that, in the cases investigated, the electrical resistance of a polycrystalline wire can be simply explained in terms of the resistance of the single crystals.—**R. O. King:** The beneficial effect of oxidation on the lubricating properties of oil. Experiments were made in conditions promoting oxidation of the lubricating oil and at constant speed and load. Friction in the circumstances falls as the temperature is raised, and generally passes through a minimum value (μ min.) at a temperature somewhat less than that of seizure (S.T.); lubricating value or performance is represented by the observed values of μ min. and S.T., which for a typical blended mineral oil were 0·0010 and 158° C., respectively at the beginning of oxidation. Viscosity increased with oxidation, but the consequent increase of fluid friction was apparent at temperatures below 50° only; at higher temperatures it decreased with the progress of oxidation and S.T. rose. Thus after about sixty hours of oxidation, μ min. diminished to 0·00045 and S.T. exceeded 300° C. The oil in a state of partial combustion remained an effective lubricant, μ being less than ever recorded for fluid friction, even with air as the lubricant. It is suggested that the active or polar molecules formed during the early stage of oxidation build up to an appreciable thickness on the adsorbed layer, and the friction observed is that on the surface of the built-up layer. The surface diminishes in rigidity in the direction of motion as the thickness of the boundary layer increases, and friction approaches zero as a surface of complete slip tends to be reached.

Physical Society, Nov. 18.—T. C. Sutton: The measurement of surface tension. A convenient method is described for measuring simultaneously the surface tension and the density of a sample of liquid. A few milligrams of liquid will suffice. The method has advantages, therefore, for the measurement of the parachors, $\gamma^{\frac{1}{4}}\rho$, of rare liquids. Volatile liquids may be used.—**L. G. Grimmett:** A sensitivity-control for the Lindemann electrometer. A circuit is given for varying the sensitivity of the Lindemann electrometer by means of one adjustment only.—**B. Lloyd-Evans and S. S. Watts:** An investigation into the flow of air in pipes. The authors examine the researches of Ombeck on the flow of air through cylindrical pipes. They obtain an expression which represents in a convenient form the phenomena that occur in a smooth-bore pipe. In particular, they separate the effects of acceleration of the gas from those of friction, and express the latter in terms of the equation suggested by Lees to fit Stanton's curve. Their results appear to justify the researches of Lees and Stanton, rather than the analysis made by Ombeck of his test figures.—**Mary D. Waller:** Vibrations produced in bodies by contact with solid carbon dioxide. Conditions under which very loud notes may be produced and maintained for a considerable time in metal objects capable of vibration, such as tuning forks, bars, discs, rings, and tubes, when brought into contact with a solid carbon dioxide block are described. Notes have also been sustained in quartz crystals. The vibration frequencies normally excited may range from about 1,000 to 15,000 ~. Lower frequencies have been excited in wires. Surface tension ripples may be produced on mercury. The vibrations are only produced by solid carbon dioxide of high density. The source of energy for producing the vibrations is the heat given up by the metal to the solid carbon dioxide.

PARIS

Academy of Sciences, Oct. 17 (vol. 195, pp. 633–684).—**Camille Matignon:** Injurious fogs. Referring to the fatal fog in the Meuse valley in December 1930, attention is directed to a noxious fog, also in the Meuse valley, which occurred on January 4, 1800, and observations of a contemporary observer are quoted.—**Maurice Fréchet:** The most general continued solution of a functional equation of the theory of probabilities in chain.—**Alfred Rosenblatt:** The unicity of solutions of partial differential equations of the first order.—**Paul Montel:** A class of meromorph functions.—**A. Toussaint and H. Girerd:** Comparison between the wall corrections in blowers of rectangular section and circular section.—**Ch. Sadron:** The standardisation of a blower for low velocities. For low velocities, less than 15 cm. per sec., the air current carrying smoke shows a curious phenomenon: the smoke thread splits up, the heavy parts fall out in drops and the interval between these drops is constant and is proportional to the air velocity. Hence this phenomenon can be utilised to measure the velocity of a very slow air current.—**Jacques Métadier:** The study of the Brownian movement in a field of force.—**A. da Silveira:** The Raman effect in solutions of cupric salts. From a comparison of the Raman spectra of solutions of copper sulphate and copper nitrate, the lines due to the sulphate ions and nitrate ions are distinguished.—**F. Wolfers:** Remarks on the Mach effect. A discussion of a recent paper by Demetrovic; analogous effects can be observed with X-rays.—**J. Thibaud and**

F. Dupré la Tour: The weakening of the nuclear radiation of beryllium in material screens.—**Auguste Le Thomas**: The influence of high proportions of silicon on certain properties of cast irons. The silicon varied from 1·1 per cent to 10·4 per cent and measurements are given of hardness, transformation temperatures, and temperatures of graphite formation.—**René Dubrisay and Guy Emschwiller**: The oxidation of iodoform solutions. Solutions of iodoform in benzene undergo rapid oxidation in daylight, with production of iodine, carbon monoxide and dioxide, but remain unchanged in the dark. After the addition of iodine and hydriodic acid, such solutions are oxidised in the dark. Oxidation differs with different solvents, and is sensitive to the presence of impurities in the solvent.—**Seailles**: The action of media with alkaline reaction on the crystallisation of the calcium aluminates and on the setting of aluminous cements. The alkalinity of the medium, defined by the hydrogen ion concentration, determines the form and the nature of the hydrated calcium aluminates which are formed starting from the anhydrous aluminates. This alkalinity causes the same phenomena and is independent of the nature of the base.—**Paul Bary and Emile Fleurent**: The influence of oxygen on the degradation of solutions of caoutchouc. The viscosity changes in rubber solutions brought about by rise of temperature are sensitive to the presence of traces of oxygen. In the absence of oxygen the change of viscosity is a hyperbolic function of the time.—**Jacques Bourcart**: The presence of a large crocodilian in the Miocene glauconitic molasse of El Kansèra and its stratigraphical signification. The bones found resemble those of *Dyrosaurus phosphaticus* but further work is necessary for the full identification.—**Georges Denigès**: The action of iodine on sea waters.—**V. Frolow**: The periodicities of the rises and falls of the Nile. A graphical study of the data available, Arabian from A.D. 621 until 1433, restarting during the eighteenth century for high water, and low water from 1838. The amplitude of the floods has become greater in modern times owing to the embankment of the Nile.—**H. des Abbayes**: Observations on the lichens of the neighbourhood of Banyuls (Eastern Pyrenees).—**R. Hovasse**: The Podamphora stage and the Ebriaceæ. The skeleton of *Podamphora Elgeri* has been regarded by A. Deflandre as arising from two different organisms: the author gives reasons for not agreeing with this view.—**André Chevallier, Jean Guillot and Pierre Chabre**: The ultra-violet absorption of certain plant and animal oils.—**G. Guittonneau and J. Keilling**: The formation of higher polythionates in the course of the solution of elementary sulphur in the soil. In addition to pentathionates described in an earlier paper, tetrathionic acid has now been isolated as the sodium salt. Thiosulphates are present in traces only.—**J. Cheymol and A. Quinquaud**: Serocalcemia and the kidney. On leaving the kidney the blood contains less calcium. After ablation of the kidney there is a temporary elevation of the proportion of calcium in the blood.

ROME

Royal National Academy of the Lincei, June 3.—**U. Cisotti**: Double tensors with a single divergence.—**B. Caldonazzo**: Hemisotropic quintuple tensors.—**J. Capoulade**: Frontier arcs rendered non-proper by the singularities of the coefficients in Dirichlet's problem for equations of the second order and of elliptic type with two variables.—**L. Fantappiè**: New demonstration of the fundamental formula for linear analytical functionals.—**L. Geymonat**: An observation on a theory of Carathéodory for harmonic functions.—**M. Picone**: Majoration of the error of approximation in the Cauchy–Lipschitz method of integrating systems of ordinary differential equations.—**O. Franceschi**: Projective study of the interior of a surface.—**M. Pascal**: Motion of a deformable body which remains similar to itself. (1) Fundamental formula and properties deduced therefrom. Abramescu's recent kinematic study of the motion of a deformable body which remains similar to itself was limited to the case of a plane body. The results obtained on extending this study to a three-dimensional body are now outlined.—**A. Kolmogoroff**: The general form of a homogeneous stocastic process.—**A. Occhialini and G. Melchiori Ranghiasci**: A simplified method for the photographic measurement of the length of spectral lines. This method consists essentially in subjecting both lens and film-holder to a succession of sudden displacements so as to obtain a number of separate images of the spectrum.—**G. A. Barbieri and A. Tettamanzi**: Contribution to the knowledge of compounds of divalent chromium. The following complexes of chromous compounds with organic bases, representing new types of chromous compounds, are described: (1) Chromodipyrridyl bromide, $[Cr^{II}(C_{10}H_8N_2)_3]Br_2, 6H_2O$, isomorphous with, and similar in chemical behaviour to, ferrodipyrridyl bromide; (2) chromous hexamethylene thiocyanate, $Cr(SCN)_2, 2(C_6H_{12}N_4.HSCN)$, and (3) chromous hexamethylene chloride, $Cr\,Cl_2, 2HCl, C_6H_{12}N_4, 4H_2O$, which belongs to an entirely new saline type; ferrous, nickel, cobalt, and manganous compounds analogous to compound (3) have also been obtained.—**O. Bottini**: Influence of exchange cations on the capillary rise of water in the soil. In one and the same soil saturated with different cations, water ascends with different velocities. This phenomenon is due principally to the part played by the exchange cations in determining and adjusting the mutual relationships between water and soil, and in particular to the influence of such cations on dispersion and swelling. In this respect the cations are arranged according to a progression which is not difficult to recognise for the lyotropic series and for the hydration series.—**Giselda Serra**: A new species of *Schizaster*. A specimen, of unknown age and origin, found in the echinoid collection of the Palæontological Institute of the University of Rome, is named *Schizaster Portisi* n. sp.—**Fausta Bertolini**: The autotomy of the digestive apparatus and its regeneration in *Holothuria*, as a spontaneous and normal phenomenon.—**T. Terni**: The development of the fin of Urodeles, on the basis of morphological and experimental investigations.—**Giulio Cotronei**: Heart transplantations between Anura and Urodeles.—**Z. Szantroch**: Investigations on intracellular fatty substances in various tissues cultivated *in vitro*. The results obtained confirm those of Kaufmann and Lehmann and indicate that neither the Ciaccio method nor the Smith–Dietrich method allows the group of substances usually known as lipoids to be distinguished with certainty from glycerol esters.—**U. D'Acona**: Does striated muscle-fibre change in volume during contraction? Micro-cinematographic investigation of muscular contraction fails to disclose any reason for assuming variations in volume of the contracted muscle fibre as a whole. It appears to prove, however, that the separate strands of the fibre widen and increase in volume at the commencement of the contraction, that they next shorten (to about forty per cent of the original length) and diminish in volume,

and that they finally resume the initial length and volume. The de-contraction takes place far more slowly than the contraction. During the passage of the contraction wave, the inter-fibrillar spaces broaden either by longitudinal displacements of liquid or by disimbibition of the fibrils.

Forthcoming Events

SATURDAY, Nov. 26

UNIVERSITY OF CAMBRIDGE, at 5—(Henry Sidgwick Memorial Lecture in the College Hall, Newnham College).—Sir James Jeans: "The Farthest Depths of Space".

MONDAY, Nov. 28

ROYAL GEOGRAPHICAL SOCIETY, at 5.30—The Rev. J. W. Arthur: "Kilimanjaro and Kenya".

ROYAL SOCIETY OF ARTS, at 8—(Fothergill Lecture).—Lieut.-Col. Guy Symonds: "Safety of Life from Fire".

TUESDAY, Nov. 29

ROYAL INSTITUTION, at 5.15—Prof. Lancelot Hogben: "Colour Change in the Animal Kingdom" (succeeding lectures on Dec. 6 and 13).

WEDNESDAY, Nov. 30

FOLK-LORE SOCIETY, at 8—(at University College, Gower Street, W.C.1).—Prof. John Read: "Alchemy and Alchemists".

THURSDAY, DEC. 1

CHADWICK PUBLIC LECTURE, at 8—(at the Royal Sanitary Institute).—Dr. T. Carnwarth: "Public Health Administration".

BROWN INSTITUTION LECTURES, at 5—(at the London School of Hygiene and Tropical Medicine).—Prof. F. W. Twort: "Bacteria in Nature".

UNIVERSITY OF BIRMINGHAM, at 5.30—(Huxley Lecture).—Sir Arthur Salter: "Next Steps in World Recovery".

BRITISH PSYCHOLOGICAL SOCIETY, at 8.30—Discussion on "Adaptation and Fatigue", to be opened by Prof. F. C. Bartlett.

FRIDAY, DEC. 2

ROYAL INSTITUTION, at 9—Marchese Marconi: "Radio Communications by Means of Very Short Electric Waves."

INSTITUTION OF MECHANICAL ENGINEERS, at 6—(Thomas Lowe Gray Lecture).—E. F. Cox: "Eight Years' Salvage Work at Scapa Flow".

NATIONAL CONFERENCE ON THE PLACE OF BIOLOGY IN EDUCATION, Nov. 30 and Dec. 1 and 3—(at British Medical Association House, London, W.C.1).—The Right Hon. Viscount Chelmsford (Presidential Address) on Nov. 3 at 11.

INTERNATIONAL SOCIETY OF LEATHER TRADES' CHEMISTS (BRITISH SECTION), Dec. 1, at 10—(at the Leathersellers' Hall, St. Helen's Place, Bishopsgate, E.C.3).—Conference on "The Swelling of Proteins". Introductory address by Prof. F. G. Donnan.

Industrial Surveys and Employment Problems*

AMONG the discussions at the recent meeting of the British Association which were given particular attention in the general Press were those arranged by the Section of Economic Science and Statistics on international migration and on the location of industries. There are, however, still many persons to whom the relation between science and problems of this type is as yet obscure. It is indeed far from being generally realised that the complex issues and intricate problems presented by international migration in the twentieth century can only be resolved by the scientific study of the numerous factors involved.

Similarly, in the national migration problems which are bound up with the unemployment problem, the bearing of scientific determination and analysis of the essential facts is only now being perceived. The social and industrial difficulties of the last two years, the magnitude of the post-War unemployment problems, have led to the active discussion of such questions as whether the present location of industries is the most economic that could be devised ; whether, under private enterprise, manufacturing industry is becoming less or more localised and whether its tendency is to render the prevention of maladjustment of labour more or less difficult.

Definite indication of the desire to ascertain the features of a rational location of industry or of the deliberate planning of social in relation to industrial resources is afforded by the invitations extended last year by the Board of Trade to various universities to conduct industrial surveys of their respective surrounding areas. It was suggested that such inquiries should cover not merely the present industrial position of the respective areas but also the prospects of early expansion and new development, having regard to recent industrial developments, and an assessment of the prospective employment capacity of the various industries in the area as a basis of estimating the probable volume of labour surplus to the requirements of individual industries within the next few years.

The mere suggestion that such an inquiry should be entrusted to the universities is significant of a changed attitude to the contribution which the

* Board of Trade. An Industrial Survey of the Lancashire Area (excluding Merseyside) made for the Board of Trade by the University of Manchester. Pp. ix + 380. (London : H.M. Stationery Office, 1932.) 6s. net.

universities have to make to the modern State. It obviously indicated an appreciation of the ability of the universities to render services which go beyond the mere training of men and women qualified to fill important positions in industry, in government, municipal or social service. The provision of men and women trained to learn quickly and accurately to grasp the essential problems of a technical problem, to analyse it and develop a plan of action, and possessing a sense of values which enables them more and more closely to relate knowledge to action or policy as their judgment matures with experience, is a function of growing importance in this scientific age, but it is only one of the ways in which the universities can serve the community. The terms of reference of these surveys suggest that the universities possess not merely the powers of conducting such social research but also the perspective and sense of values which are essential to the presentation of an authoritative and impartial analysis of the facts thus assembled.

There have now been presented to the Board of Trade no fewer than five such surveys. A survey of south-west Scotland has been completed by the University of Glasgow, while the University of Wales, Cardiff, has issued its report on the South Wales area. Surveys of the Merseyside area and of the remaining Lancashire area carried out by the Universities of Liverpool and Manchester respectively have followed that on the industrial area of the north-east coast by the University of Durham. The five surveys together not only provide a most valuable analysis of industrial conditions in the areas covered but also afford a basis for assessing the importance of such contributions of university resources to the national welfare.

In the first place, it is pertinent to observe that the presentation of such a report by a university confers upon the report an authority and an assurance of impartiality which is not easily otherwise obtained. The industrial situation has frequently suffered from *ex parte* statements which differed widely in themselves but could not be verified against some reliable and independent authority. An accurate estimate of the problem presented by surplus labour is impossible apart from some such inquiry and analysis, and accuracy and authenticity are essential if confidence is to be placed in the deductions or recommendations based thereon. Mr. A. G. H. Dent, in a paper before the Department of Industrial Co-operation at the recent British Association meeting, specially stressed the value of statistics obtained by absolutely reliable authority as a means of avoiding suspicion and misunderstandings in any industrial dispute.

The Lancashire survey brings to light the high incidence of unemployment among workers in the age group 18–24 years, and sets in its true significance for national or social economy this incidence upon workers at a period in the working lives when they should be rapidly approaching maturity of industrial skill and adaptability and when they should be most capable of moving into other industries or localities. Similarly, the analysis of the inflow and outflow of labour is characterised by a concern for social consequences that could scarcely have been found in any inquiry initiated by industry itself, and leads to definite suggestions for regulating the recruiting of labour for the cotton industry in all districts. The survey demonstrates that in the absence of any organised effort by the cotton industry or the State to control the flow of juveniles into the industry, heavy unemployment and restricted earnings of adults did not deter very large numbers from entering the industry. Nor is there any full and accurate information from year to year as to the numbers entering the industry at the age of fourteen years, or their progress during their early working years. The tracing of the industrial history of juvenile workers in this way is an obvious preliminary to the difficult task of regulating entry and avoiding blind-alley occupations, apart from the opportunity for an attempt to secure for every entrant the advantage of a reasonable period of skilled instruction in his occupation.

The analysis of the position of the cotton industry presented by the report of the University of Manchester emphasises the importance of such independent social research. Thus the immobility of labour in Lancashire is largely due to social factors—the prevalence of the family income, the preponderance of female labour, the custom of women workers continuing at work after marriage, the high concentration of unemployment in relatively isolated districts, and the reluctance of workers to recognise the existence of a permanent surplus. Such proposals as the abolition of the short-time working and under-employment of labour which result from the existence of permanent surplus capacity of capital equipment and labour would reveal the real extent of the labour surplus, but so long as the displacement and recruitment of labour is unorganised, the burden

of unemployment will not be distributed in a manner causing a minimum of loss or damage to the labour resources of the industry.

Nowhere is the advantage of such independent research greater than where it touches the effect of technical changes on the demand for labour. So far as the cotton industry is concerned, it seems clear that no appreciable part of the existing surplus of labour can be attributed to technical 'rationalisation', but there are signs that changes are impending which will radically increase the physical output per person employed and consequently displace labour, if the aggregate output remains the same. The report gives an unbiased analysis of four new methods of production which are considered to present the most serious labour difficulties and its observations cannot be ignored by either side. The 'more looms per weaver' system presents the most serious problems, bringing about a decrease in production per loom but an increase in production per weaver; while the weekly earnings of the weaver are maintained or slightly increased, the weaving labour costs fall and also total costs per unit of output. The report observes that in the negotiations between employers and trade unions, the problem of mitigating the effects of further additions to the surplus of labour in the weaving districts does not seem to have been scientifically examined and urges as an essential condition that collective bargaining should be defended against the inclination of individual firms to break away from existing wage agreements. Given collective bargaining, it is considered that there is no reason why the introduction of the system should not be planned so far as is practicable to give security of employment to the workers who are retained and to regulate displacement so that the burden falls on those best able to bear it.

The value of this survey is equally apparent in its discussion of the position of the expanding industries and of the possibilities they offer of absorbing the surplus of labour from other industries. It is, however, evident that the survey is only a start towards the handling of the unemployment problem on scientific lines: "Lancashire's difficulties," says the report, "are essentially of the type which calls for long-distance treatment and far-sighted planning, based upon the intensive research of a continuing character, and the Survey has provided the opportunity for a critical examination of the existing statistical material and has revealed many serious gaps in the information which must be made available if continuous investigation is to yield the most useful results." The report proceeds to emphasise the importance of compiling much more frequently than at present statistical material, the primary and chief value of which lies in its utility in economic research. "Increased funds devoted to the wider and more complete charting of the national economic system would be a sound investment, despite the urgent campaign for national economy."

The report punctuates its plea for such research by concrete proposals addressed alike to the national and local authorities, to trade unions and to employers' associations, for the collection of the specific statistics required. It thus envisages a definite field of social economic research which is fully in keeping with the programme advocated, for example, by Prof. W. McDougall. These surveys attest both the resources and the capacity of the universities to undertake such research and there is little doubt that it would be to the great advantage of the community if some of the effort at present directed to the advancement of the physical sciences were directed to these ends.

Apart from the corrective to that dangerous tendency in industry and politics to ignore or avoid unpleasant facts and disregard the consequences of a selfish or sectarian policy, research of this type has other advantages. It gives a striking demonstration of the capacity of the scientific worker for leadership and relates university life intimately with the main stream of national life; the recent suggestion of Mr. Alan Chorlton, M.P., for the formation of a Research Council in Manchester appears to be prompted by the survey and indicates the educational value which such research can possess. It also encourages a widespread appreciation of the value of scientific training and technique in the solution of social, economic, and industrial problems. Both factors should promote the production and acceptance of leaders and administrators whose qualifications for office include the indispensable capacity of assessing at first hand the technical factors in the problems they have to solve. Without such capacity, there is no prospect of the planning of our national material and social resources on national lines, of their being wisely co-ordinated with world resources in a spirit of international co-operation, or of that right relation of knowledge to action upon the rapid evolution of which the security of civilisation depends.

Κτῆμα ἐς ἀεί

Faraday's Diary: being the various Philosophical Notes of Experimental Investigation made by Michael Faraday, D.C.L., F.R.S., during the Years 1820–1862 and bequeathed by him to the Royal Institution of Great Britain. Now, by order of the Managers, printed and published for the first time, under the editorial supervision of Thomas Martin. With a Foreword by Sir William H. Bragg. In 7 vols. Vol. 1: Sept., 1820–June 11, 1832. Pp. xxv + 430. Vol. 2: Aug. 25, 1832–Feb. 29, 1836. Pp. xvii + 467. (London: G. Bell and Sons, Ltd., 1932.) 7 vols., £12 12*s.* 0*d.* net.

THE Faraday diary is not a find in the spectacular sense of that of the Boswell papers. Faraday's laboratory notebooks, various lecture notes and account books, the notes which he took of lectures by Tatum and by Davy, with specimens of various books bound by his own hands were gifted, as the expressive Scots word has it, to the Royal Institution by himself or by his widow. No mystery surrounds these possessions; no ebony cabinet has been rifled to reveal manuscripts long lost and long sought, as those destined to make the name of Boswell a by-word in the mouths of the examiners of would-be doctors of philosophy. These treasures have been jealously preserved in the archives of the Royal Institution; privileged observers have been permitted to see and to handle them.

Nonetheless, it is a red letter day which has seen the publication, even in a strictly limited edition, of the laboratory notebooks. These, ranging as they do over the most fruitful years of Faraday's life, afford a picture of the development of the mind of a great genius, of his gropings in the dark, and of those flashes of insight which have led to a solution of some of the fundamental problems of physical science—a picture which will be, in the phrase of Thucydides, 'a possession for all time'.

The publication of these notes is all the more valuable, inasmuch as the extant biographies leave something to be desired. The biographical traditions of the Victorian, and the paulo-pre-Victorian era were, despite the examples set by Lockhart and by Trevelyan, arid and unliving. The two- and three-deckers of the period, equally with the series of smaller volumes in which great reputations were decently buried (how Mark Pattison's "Milton" even now stands out from the ruck!), all serve to show that the contemporary tradition was at one with the tradition of portraiture—what has been described as a head sticking out of a suit of clothes.

Faraday has not escaped. The full-dress biography by Bence Jones is, despite its value as a storehouse of facts, a trifle heavy; Tyndall's affectionate little volume tends to slip, as was Tyndall's wont, from sentiment into sentimentality; Silvanus Thompson's study, by far the best account of Faraday's scientific work, still bears some of the stigmata of the age. The most lively contemporary account of Faraday's vivid and eager personality is to be found in the pages of a lesser-known sketch—that written in 1870 by J. H. Gladstone.

Every document, then, that will help to provide a complete portrait of the man in his habit as he lived, is of importance, for Faraday's is an intriguing personality, not alone in the genius that it shows, in its transparent honesty, gentleness and almost excessive humility, but also in its baffling simplicity. Cheerfulness, eagerness, playfulness are prominent—a contemporary draws a pleasant picture of a British Association dinner at Ipswich in 1851, at which Faraday amused himself by cutting boomerangs of card and projecting them across the table at his friends—but over all and dominating all is a single-hearted devotion to the advancement of science which can rarely have been surpassed in the long history of the development of scientific thought.

This devotion had strange consequences, among them a complete indifference to political events of the first magnitude. Is there any other instance on record, in the development of an active-minded young man of four and twenty, of such an entry as occurs in Faraday's journal for March 1815—three months before Waterloo? "I heard for news that Bonaparte was again at liberty. Being no politician, I did not trouble myself much about it, though I suppose it will have a strong influence on the affairs of Europe."

Nor, great as was his private benevolence, does Faraday seem to have taken any pronounced interest in schemes for social betterment. He lived for his science and his religion, and neither material rewards, nor the highest offices, had the slightest attraction for him. To his friend, pressing him to accept the presidency of the Royal Society, "Tyndall," he said, "I must remain plain Michael Faraday to the last; and let me tell you now, that if I accepted the honour which the Royal

Society desires to confer upon me, I would not answer for the integrity of my intellect for a single year."

The volumes before us testify eloquently to this devotion. They cover the period 1820–1836, and so include some of the most fundamental of Faraday's discoveries. The story of the isolation of benzene, and the examination of its properties, the liquefaction of gases, and the results of that concentrated ten days' work, the centenary of which was celebrated last year, may be read now as they were first set down by Faraday in the heat of the chase.

We do not here, however, attempt any detailed analysis of the two volumes now published. That may more fittingly be done at a later stage, when an opportunity will be afforded to pass in review the contents of the seven stately volumes which are to form the complete diary. Meanwhile we may say with assurance that the publication of the first two volumes has amply justified the policy of the managers of the Royal Institution. The diary is much more than a record of laboratory experiments and figures; it provides the material for an analysis of the development of Faraday's thoughts concerning the problem in hand. Its value, as we have before emphasised, lies in the opportunity which it gives, to a future historian of physical science, to limn a picture of the genius of Faraday and, indeed, of some of his personal qualities which would be quite impossible to anyone who was not fortunate enough to have access to the diary. The entries are, on the whole, restrained enough; here and there one may find italicised a '*very good*'; yet the general impression left after a perusal of the pages of these volumes confirms the pen picture of the "young-looking man of about thirty years of age . . . his cheerfulness of disposition often breaking out in a short crispy laugh, but thoughtful enough when something important is to be done". We can visualise, too, the experimenter of mature years who, ready for the day's work, would "descend into the laboratory, give a quick glance round to see that all was right, take his apron from the drawer, and rub his hands together as he looked at the preparations made for his work. There must be no tool on the table but such as he required. As he began, his face would be exceedingly grave, and during the progress of an experiment all must be perfectly quiet; but if it was proceeding according to his wish, he would commence to hum a tune, and sometimes to rock himself side-ways, balancing alternately on either foot. . . . He would put away each tool in its own place as soon as done with . . . and he would not unnecessarily take a thing away from its place. . . . No bottle was allowed to remain without its stopper; no open glass might stand for a night without a paper cover; no rubbish was to be left on the floor."

More than anything else, the cumulative effect of the day by day entries in the diary is to throw into relief Faraday's intense desire to see and do everything for himself. No experimental fact was to be taken on trust; as he himself writes to Becker: "I am never able to make a fact my own without seeing it. If Grove, or Wheatstone, or Gassiot or any other told me a new fact, and wanted my opinion either of its value, or the cause, or the evidence it could give on any subject, I never could say anything until I had seen the fact. For the same reason I never could work . . . by students and pupils. All my work had to be my own." The same characteristic appears in a pleasant record by Mallet of a visit which he paid to Faraday in order to show him how slips of Muntz's yellow metal, ordinarily flexible and tough, became at once rigid and brittle when dipped into a solution of pernitrate of mercury. The demonstration was made, Faraday standing nearby. He made no comment whatever, but picked up a piece of the metal, bent it, dipped it into the solution and broke it into small pieces. Then, "Yes," said he, "it *is* pliable, and it *does* become instantaneously brittle."

So when Tyndall showed him the then novel phenomenon of calorescence he "looked on attentively, putting on his spectacles to observe more carefully, then ascertained the condition of the experiment and repeated it for himself; and now, quite satisfied, he turned with emotion to Dr. Tyndall, and almost hugged him with pleasure."

The complete diary will form a commentary of inestimable value on one of the most romantic lives in the history of science. Looking into its volumes in retrospective mood, we may see something of the mettle of the bright-eyed newspaper lad, the bookbinder's apprentice, the young laboratory assistant, widening his knowledge, and testing his strength at the meetings of the City Philosophical Society; the pages of the earlier volumes will show him in the fulness of his powers, enriching chemical and physical science by discovery after discovery of the first magnitude, yet still retaining that boyishness of disposition

which sent him with his attendant "to Astley's, to see the horses" to celebrate the occasion when he had first made "the wires go round the magnet". It may be that the last volume will show something of that pathetic and yet not wholly painful decline to which he himself alludes in the Friday evening discourse on platinum which he delivered in February 1861, six years before his death, a decline which left him broken in mind and frail in body, yet still preserving his gentleness of spirit and thought for others, still able to find beauty in the rolling of a thunderstorm and the hues of a sunset.

But the story should not end here; there are, surely, records still unpublished to which Mr. Martin may apply his energy and his scholarship. More than all, there still remains to be written an authoritative exposition of the origin and growth of the Royal Institution. Those who know something of the contributions made by London to the advancement of science know, too, that in the vastness of London, individual contributions of the first importance are apt to be lost. Of these contributions none is more weighty than that made by the Royal Institution. The part which it has played in fostering research and in popularising knowledge is well known. From its earliest days, when it was associated with the dramatic discoveries of Davy, it has been fortunate; all Faraday's labours are indissolubly connected with its laboratories, and the work of succeeding directors has added to the lustre of these early discoveries. Even to-day, Faraday's personality dominates its work. To his genius for exposition we owe the inception of the Christmas lectures, and an institution which is probably unique in the scientific world—the Friday evening discourses. Is it too much to hope that the recrudescence of interest in Faraday's life and work which is evidenced by the publication of the diary may extend to the walls of the Institution wherein he laboured so long, and for which he had so deep and so lasting an affection? The story is no jejune one—it is picturesque enough in its details, and touches the development of more than a century's physical science at many points of fundamental interest. Incidentally, it will afford an opportunity to do justice to the memory of a natural philosopher, the story of whose life has been strangely neglected—Faraday's intimate friend and successor, John Tyndall.

It would be ungrateful to close this notice without comment on the skill and discretion which the editor has shown in the by no means easy task which he has faced. It is not difficult to see that, in turning into print some four thousand pages of manuscript written *currente calamo* and illustrated by rapidly drawn pen sketches, various delicate questions will arise concerning the reproduction of the actual punctuation, wording, spelling, and contractions. Mr. Martin has solved these problems with a degree of success that testifies alike to his scholarship and acumen. He has left the text largely to speak for itself, and confined his notes to the minimum necessary for elucidation. In congratulating him on the completion of the first portion of his task, we can offer him no better wish than that the rest of his work may attain the high standard of that already published.

ALLAN FERGUSON.

Botanical and Horticultural Biographies

Curtis's Botanical Magazine Dedications 1827–1927: Portraits and Biographical Notes. Compiled by Ernest Nelmes and William Cuthbertson. Published for the Royal Horticultural Society, London. Pp. xxi + 400 (100 plates). (London: Bernard Quaritch, Ltd., 1931.) 30*s*.

THE intimate relationships subsisting between botany and horticulture are nowhere more clearly seen than in the history of *Curtis's Botanical Magazine*. Founded in 1787 by William Curtis, the author of the "Flora Londinensis", the *Botanical Magazine* now includes more than nine thousand hand-coloured plates, with descriptive letterpress, of plants grown in gardens, public or private, and at the present day under the able editorship of Dr. O. Stapf it enjoys a higher botanical reputation than ever before.

The volume under review contains portraits and short biographies of the founder and of the hundred eminent botanists and horticulturists to whom the volumes of the *Botanical Magazine* have been dedicated during the century 1827–1927. Its publication has been made possible by the generosity of Mr. William Cuthbertson, chairman of Messrs. Dobbie and Co., of Edinburgh. The copying of the portraits has been carried out by Mr. G. Atkinson, artist at the Royal Botanic Gardens, Kew. More than half are reproduced from photographs, engravings and drawings in the Kew collection, the remainder having been obtained from various sources. Only one is wanting, that of Mrs. Wray,

of Oakfield, Cheltenham, to whom vol. 67 was dedicated in 1841. A special request is made that any reader who may know of a portrait of this lady should send particulars to the secretary of the Royal Horticultural Society. Owing to the varied nature of the originals, the standard of the portraits is very unequal, some being exceedingly good, while others, such as that of H. J. Elwes, are unsatisfactory.

The biographical notes are with few exceptions written by Mr. E. Nelmes, assistant botanist at Kew, who was also responsible for assembling the portraits. They are of a general length of 1½–2 pages, and summarise very clearly the principal events in the lives of the persons concerned. Much of the information supplied is not readily accessible elsewhere, and the work will be indispensable to all interested in botanical and horticultural biography. The general absence of critical estimates of the character and scientific work of botanists of the present and past generation is to be regretted, since it makes some of the accounts appear rather colourless to those who know the men concerned. For this, however, the plan of the work and the limitations of space appear to have been mainly responsible. Apart from this minor defect, the biographical sketches are excellent.

Among the botanists commemorated are three keepers of the Kew Herbarium, D. Oliver, J. G. Baker and W. B. Hemsley, and three directors of the Gardens, J. D. Hooker, W. T. Thiselton-Dyer and D. Prain, while the Royal Botanic Garden, Edinburgh, is represented by J. H. Balfour and I. B. Balfour. More on the horticultural side are G. Nicholson and W. Watson (Kew), R. I. Lynch (Cambridge) and F. W. Moore (Trinity College, Dublin, and Glasnevin). Among those distinguished in both botany and horticulture are J. T. Mackay, David Moore and M. T. Masters. Investigators of the various floras of the British Empire include, besides the above-mentioned botanists, Wight, T. Thomson, G. King and C. B. Clarke (India), Thwaites and Trimen (Ceylon), Ridley (Malay Peninsula), F. von Mueller (Australia), Bolus and Medley Wood (South Africa).

The botanical collectors comprise Welwitsch and Gustav Mann (West Africa), Kirk (East Africa), and Augustine Henry, E. H. Wilson and G. Forrest (China). Henry made a name for himself in a different field by the "Trees of Great Britain and Ireland", written in collaboration with Elwes, who is also included in the volume, and Wilson published numerous works on botany and horticulture including the "Lilies of Eastern Asia", "The Cherries of Japan", and "A Monograph of Azaleas", the last-mentioned written in conjunction with Rehder. Vol. 95 (1869) was dedicated to Walter Fitch, the unrivalled botanical artist, whose published drawings are estimated at ten thousand.

The United States is represented by Torrey, Asa Gray and Sargent, who contributed so much to our knowledge of the North American flora, Germany by Salm-Dyck and H. G. Reichenbach, and Russia by F. E. L. Fischer and E. Regel.

Among the amateur botanists included are James Bateman, the author of the "Orchidaceæ of Mexico and Guatemala", Dean Herbert, a great authority on bulbous plants, M. J. Berkeley, the cryptogamic botanist, George Maw, who published a monograph of the genus *Crocus*, and John Ball, who is perhaps best known by his Alpine guide. The following may be singled out among the many prominent horticulturists whose portraits and biographies are given: W. T. Aiton, Joseph Sabine, Max Leichtlin, H. L. de Vilmorin, and W. Wilks, whose name will always be associated with the Shirley poppy.

The volume reflects great credit on all concerned in its production.

The Moa in New Zealand

The Mystery of the Moa: New Zealand's Avian Giant. By T. Lindsay Buick. (Published under the Auspices of the Board of Maori Ethnological Research.) Pp. xvi + 357 + 27 plates. (New Plymouth, N.Z.: Thomas Avery and Sons, Ltd.; London: Francis Edwards, Ltd., 1931.) 15*s*.

PERHAPS no event in the ornithological world was more astounding than the discovery of the bones of the largest known bird, the moa, which existed in New Zealand, the fringe of the great sunken southern continent. The first mention of this bird in literature was made in Polack's "New Zealand", 1838, but no notice was taken of this by scientific men. Later on, Harris obtained a portion of a bone and gave it to Dr. John Rule of Australia, who eventually brought it to England. Prof. Owen examined it but was sceptical about its being the bone of a bird, but on further examination he was convinced that it

was indeed part of the skeleton of a large extinct flightless bird. This pronouncement was read before the Zoological Society of London on Nov. 12, 1839, and was published in the Society's *Transactions*. This bone became the type of the genus *Dinornis* which Owen introduced on Nov. 28, 1843, in the same publication, vol. 3, p. 235.

Soon afterwards the scientific world hungered for more examples and so New Zealand was exploited and thousands upon thousands of bones were brought to light, so that to-day no museum of any size is without some part of a skeleton of one of the many species of moa. From maps on pp. 163–164 of Mr. Lindsay's book showing the places where finds are recorded we gather how plentiful these birds were.

Mr. Lindsay gives the history of the Moa from the fossils of the Pliocene or post-Pliocene times when they were plentiful, up to their extinction in the seventeenth or even as some think into the eighteenth century. Many different lots of feathers are extant showing their formation and colour.

The author accepts the theory of Mr. Percy R. Lowe that these birds are descended from birds which never flew. They varied in size from fourteen feet or more in height to little fellows of about four feet, and appear to have been more common in the South than in the North Island.

It is surprising how much we are told of the life history of these birds; we know what colour they were; that in June and July they were fattest; the nest of one species is described as are the eggs of several forms; they lived on a vegetarian diet and thousands of their 'crop stones' have been found. Some skeletons were found in caves and numbers were found together in swamps, as many as eight hundred skeletons in one place. Many theories as to how these large heaps of bones were amassed are put forward, only to be rejected. Why did this bird become extinct? Was it change of climate? Was it due to man? Or had they served their turn and passed on?

Many different classifications have been advanced but the author accepts that of Oliver in "New Zealand Birds"; that is two families, five genera and twenty-two species. A bibliography and index complete the work.

This book will appeal not only to ornithologists, but also to a much wider circle of readers; in fact to all who are interested in the story of past ages, and whom it may amuse to speculate on the mystery of vanished races.

Short Reviews

The Quantity and Sources of our Petroleum Supplies: a Review and a Criticism. By Prof. J. M. Macfarlane. Pp. xiv + 250. (Philadelphia: Noel Printing Co., Inc., 1931.) n.p.

READERS versed in the literature of petroleum will recognise in this book the author of "Fishes the Source of Petroleum", published some nine years ago, who now reappears with an extensive thesis of oil origin in which metanemerteans, invertebrate fresh-water animals of widely dispersed occurrence, and apparently related conodonts, are invoked as fundamentally contributive mother substance. The argument is that life originated and thrived in fresh-water areas, spreading both landward and seaward; of this life, the most abundant group was the metanemerteans, the representatives of which are now found in fresh and salt water and moist land-surfaces. Certain strata yield conodont teeth, closely resembling pharyngeal teeth of the metanemerteans, in association with prolific oil pools. By focusing attention on environments, as illustrated by three oil-bearing formations chosen in North America, it is shown that seismic and volcanic phenomena intervened in the evolution thereof.

Great stress is laid on the consequential dust product and on its chemical and petrological composition. Such dust, falling into fresh or salt water, changed into a soft colloidal condition or hydrogel, upset the balance of quiescent aquatic life and resulted in wholesale instantaneous destruction of the most sensitive (sic) of all animals, fish. Thus their bodies were enveloped along with diatoms, algæ, etc., in a shroud of rock-dust; pressure promoted chemical reactions between the alumino-silicic substances and hydrocarbons giving rise to "an alumino-silicate of oil and protein", or definite mineral compound, the "kerogen" of Crum Brown and Scottish oil shale fame. Regard this kerogen as a complex semi-colloid or colloid subject only to change with rise of temperature; divert such changes into separate channels according to the geochemical conditions obtaining at particular epochs, and thus are oil shales on one hand, petroleum on the other, given existence. This is an ingenious philosophy, combining all the weaknesses of the organic and inorganic theories of oil origin, with few of the merits of either, and, moreover, an excellent example of the danger of generalising on two or three particular occurrences. This is a book to look into, but difficult to take seriously.

The Journal of the Institute of Metals. Vol. 48. Edited by G. Shaw Scott. Pp. xi + 350 + 33 plates. (London: Institute of Metals, 1932.) 31*s.* 6*d.* net.

IN the May lecture to the Institute of Metals, Dr. Körber, of Düsseldorf, describes his investigations into the plastic deformation of metals. These are

well known to many from the original German publications, but the convenient and well illustrated summary here given will be of much value to metallurgists, being rich in suggestions bearing on the general problem of deformation. As has frequently been the case in recent years, the light alloys form the subject of a number of communications, perhaps the most striking of which is the description of the protection of magnesium and some of its alloys by the deposition of a film of selenium. The film is self-healing to a certain extent, and serves as a basis for paint or enamels, which it causes to adhere firmly. The 'fogging' of nickel is shown to be due to the action of sulphur compounds in the presence of moisture, a basic sulphate being the final product. It is largely inhibited by a preliminary formation of a thin film of sulphide.

A general discussion on the testing of castings brings out fundamental divergencies of view, some authorities holding that tests should be made on test pieces cast separately, whilst others hold that the test pieces should be cut from the actual casting. As the only conclusive test would involve the destruction of the casting, and even the best of castings will vary greatly in properties from one part to another, it would seem reasonable that the former plan should be adopted, and this view is held widely in Great Britain. The volume contains nearly twenty distinct communications.

The Subject Index to Periodicals, 1930. Issued by the Library Association. Pp. ix + 298. (London : The Library Association, 1932.) 70s.

THIS volume has been compiled under the direction of Mr. T. Rowland Powel and contains about 28,000 references. The headings are arranged in alphabetical order by subjects and are mainly chosen from the alphabetical subject headings of the Catalogue of the Library of Congress of the United States. Under each heading the articles are arranged alphabetically by the authors' names.

The range of subjects extends far beyond science even when taken in the widest sense, but fiction and verse are excluded. To restrict the size of the "Index", periodicals already indexed by certain well-known publications such as *Engineering Abstracts, Index Medicus, Journal of the Society of Dyers and Colourists, Revue de Géologie, Royal Meteorological Society's Bibliography, Science Abstracts* and *Textile Institute Journal* are not dealt with. Yet when these exceptions have been made, there remain no less than 545 English and American periodicals that have been indexed for this catalogue. In addition to these, 24 French, Belgian and Swiss, 20 German and Dutch, and two Italian periodicals have been dealt with.

In spite of attempts that have been made to induce authors to send their papers only to well recognised periodicals, it is still true that important work may be found hidden in publications the very names of which are unknown to most men of science. It is the function of the "Subject Index to Periodicals" to reveal such hidden papers. Such work should be done by international co-operation, but until this is possible, the Library Association should receive every encouragement to continue this series of annual indexes.

Johann Kepler 1571–1630 : a Tercentenary Commemoration of his Life and Work. Pp. xii + 133 + 2 plates. (Baltimore, Md.: The Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1931.) 13s. 6d. net.

THIS little book consists of three addresses given before the History of Science Society in joint session with the American Association for the Advancement of Science, together with a brief introduction by Sir Arthur Eddington and a bibliography of all the important works of Kepler. In "Kepler as an Astronomer", Dr. W. C. Rufus gives a clear and concise account of his subject which adds point to Eddington's picture of Kepler as the forerunner of the modern theoretical physicist. This address also contains general biographical particulars, in addition to a description of his work as an astronomer.

Kepler's mathematical achievements are perhaps not so well known, although they are of great importance—particularly in the infinitesimal calculus, the simplification of computations and the use of logarithms. These and other contributions to mathematics are described by Dr. D. J. Struik; while Kepler's philosophical and mystical outlook, which was so intimately related to his other work all through his life, is dealt with by Dr. E. H. Johnson.

In spite of some inevitable overlapping of subject matter, and the limitations imposed by its size and origin, the book is a useful contribution to the history of astronomy. The bibliography, in particular, compiled and annotated by F. E. Brasch, chief of the Smithsonian Division of the Library of Congress, should be most valuable.

Flowerless Plants. By Dr. Dukinfield Henry Scott. (Part 2 of An Introduction to Structural Botany.) Tenth edition, re-edited by F. T. Brooks. Pp. xvi + 332. (London: A. and C. Black, Ltd., 1932.) 7s. 6d. net.

THIS well-known book on the cryptogamic plants needs no introduction and the fact that it is now in its tenth edition speaks well for its success. This edition has been re-edited by Mr. F. T. Brooks, with the result that the new types *Peronospora, Saccharomyces* and *Euglena*, have been added. All three additions are important, representing a plant disease, a simple fungus of great economic importance, and a flagellate. *Cladothrix* has been omitted. The results of recent researches in Algæ and Fungi have been incorporated so far as is possible into the text. Written by Dr. Scott, and now revised with the advice and help of well-known specialists, the new edition of this book will continue to be an authoritative introduction to the subject.

Wood Anatomy as a Link between Botany and Forestry*

By B. J. RENDLE

THE conception of forestry as being ultimately dependent for its advance upon the interaction of a number of more or less independent basic sciences is a familiar one. The problems associated with the tree considered as a plant and with the forest considered either as an ecological unit or an artificial crop call for special methods of attack which, while primarily concerned with some aspect of forestry, can incidentally contribute to the general fund of botanical knowledge. The study of wood anatomy, with special reference to the production and utilisation of timber, is a case in point. In modern times this somewhat specialised subject has advanced along several different lines according to the points of view of the investigators concerned. The demand for practical methods of identifying and investigating the physical properties of commercial timbers has stimulated the study of species in this category. This has naturally been carried out more with reference to the important timbers of certain geographical regions than with botanical groups, and the woods of the north temperate zone in particular have received more than their fair share of attention.

In Germany, long before the end of the last century, certain of the timber-producing species of outstanding importance to Continental forestry practice were submitted to intensive studies of their anatomical-technical characters, which, besides yielding results of direct practical application, were of value in instigating further research in the peculiar problems of plant physiology which are associated with the great size and long life of trees. More recently, the opening up of botanical exploration in the tropics has offered a wide field of investigation in wood anatomy. Numbers of new genera and species of great potential value as a source of timber incidentally provide material for the study of systematic anatomy which for richness and variety is far superior to the limited and rather specialised arborescent flora of the north temperate regions.

Botanical exploration in an entirely different direction, geological rather than geographical, has also been the means of advancing our knowledge of the structure of wood, particularly as regards the gymnosperms. Study of the structure of fossil plants has been of the greatest importance in the development of the subject; it has even been observed that at one time woody plants were better known anatomically in a fossil than in a living condition, and it is safe to say that some of the most valuable studies of coniferous woods have been prompted by a desire to elucidate the relationship of their fossil allies and their connexion with recent forms. These researches have resulted in the formulation of criteria capable of wide application, and in this way palæobotany has probably had a stronger influence than either taxonomy or physiology on the progress of wood anatomy.

In considering the systematic value of wood characters, as with any other part of a plant, the first essential is to recognise the kinds of characters that are to be found. Different writers have divided characters into various classes and sub-classes, each with a more or less descriptive name, but for the present it is only necessary to refer to the two main divisions, namely, those which can be regarded as adaptations to environment, that is, 'biological characters', and those which have no apparent relation to the environment and remain unaffected by variations in the conditions of growth; for these the term 'inherent characters' seems to be the most appropriate.

It is abundantly clear that the anatomical structure of wood is a product of two factors, heredity and adaptation, and the successful employment of anatomical characters for systematic purposes depends on our being able to distinguish constant, inherited characters from those which are due to the influence of environment. In the course of generations of research, botanists have arrived at a fair idea of what morphological characters are constant, and to what extent they can be interpreted as indicating relationships. But in the case of wood there is relatively little information on this point and the need for further work of this kind is most pressing. The reason for this is not far to seek. The plants which are the subject of investigation in most fields of applied biology are generally available in a more or less complete condition, or at the least, their naming and classification is based on a study of those parts which are easily obtainable, but in the case of trees the difficulty is that the plant is such a large object; it is a laborious undertaking to examine the complete range of morphological and anatomical variation in a single tree, and when it becomes necessary to take into account the further variations induced by different conditions of growth, the problem assumes a much more formidable aspect.

Systematic botanists who have had to concern themselves with the critical study of trees from herbarium specimens are familiar with the morphological variation which occurs and which has often led to two or more specific epithets being attached to the same species when the trees have been described and named on incomplete botanical material. The similar variation in the structure of wood has not been sufficiently realised by all anatomists and this has in turn resulted in descriptions and keys, based on a study of inadequate material and on characters

* From a paper read before a joint meeting of Sections K (Botany) and K* (Forestry) of the British Association, at York, on Sept. 5.

which are not specific at all but only due to different conditions of growth, being used to differentiate between species. Many of the early researches in wood structure were directed towards the study of the size of the wood elements and their distribution within the growth ring, chiefly for purposes of identification. It is not yet fully realised in certain quarters that these features vary from tree to tree and that they vary more widely in different parts of the same tree.

Now, although this variation is considerable, the position of affairs is not so hopeless as it might appear at first sight. It will not be necessary to cut and examine microscopically the structure of hundreds of sections from dozens of different trees in order to obtain a reasonably accurate picture of the typical wood structure of every species. But it is necessary to examine in detail a few species exemplifying selected types of structure in order to ascertain the limits of variability of each diagnostic feature and to discover if possible the laws governing such variation. Critical anatomical surveys of this kind can only be undertaken by institutions in a position to obtain carefully selected trees and to examine them according to an ordered system of routine.

At the Forest Products Research Laboratory at Princes Risborough, the main consideration which underlies investigations in wood structure is naturally the influence of structure on the technical properties of the timber. There is no need to labour the point that in technological research one of the first essentials is to discover as much as possible about the physical nature of the material concerned. The cellular structure of wood is one of the most important factors in determining its physical properties, and a close correlation exists between changes in structure and changes in technical properties. The variation in the properties of timber grown under different conditions of climate, soil and sylviculture is one of the big disadvantages of the use of wood in industry for purposes which are in any degree exacting. The problem before us is to investigate the structure of a sufficient quantity of each species, grown under different conditions and in different parts of the country, so as to obtain an idea of the normal range of variation that is likely to occur. The same timber that is examined anatomically in the Laboratory is also subjected to technical tests. In this way its general quality is correlated with the growth features, thus indicating to the forester the conditions of growth necessary to produce first quality timber. At the same time, the results of these investigations are the means of increasing our knowledge of the general principles underlying the relation between the structure and the properties of wood, knowledge which is in demand for assessing the technical value of wood from an examination of its structure and for the proper understanding of the peculiar behaviour of wood under varying conditions of temperature, humidity and so on.

The lines of research that have been briefly outlined above, although directed primarily towards the solution of economic problems, are incidentally of importance in increasing our knowledge of the systematic anatomy of wood, and by virtue of their somewhat intensive character they are of special value in enabling us to distinguish between inherent and biological characters. From the severely practical point of view, this is of obvious importance in order to place the identification of timber specimens on a sound scientific basis, and there is ample evidence that the anatomical characteristics of wood can usefully be taken into account in the solution of taxonomic problems. There can be no serious suggestion of attempting a natural classification of woody plants on the sole basis of their vascular anatomy, but on the other hand there is no gainsaying the fact that the nearest approach to the ideal system of classification will be based on a complete knowledge of the external morphology and internal anatomy of plants. Wood anatomy is essentially auxiliary to taxonomy but it is an auxiliary that botanists cannot afford to neglect; it is, for example, of special value in throwing light on the systematic position of anomalous genera and provides a valuable test of the homogeneity of a family.

From the very nature of the subject the study of wood anatomy is confined to a comparatively small number of specialists, most of whom have been led thither by way of forestry or forest products research. In the belief that mutual benefit would result from some measure of organised co-operation between workers in different parts of the world, the opportunity offered by the Fifth International Botanical Congress at Cambridge in 1930 was taken by a few interested parties to discuss ways and means of effecting such co-operation. Eventually an International Association of Wood Anatomists was formed, which has as its object the advancement of the knowledge of wood anatomy in all its aspects; this Association seeks to achieve its object by enabling workers in the same field to get in touch with each other, by facilitating the exchange of ideas, information and material and by working towards standardisation in terminology and methods of description.

Co-operative work has already been started on the preparation of a polyglot glossary of terms used in describing woods. Anyone who has had occasion to study the recent literature of the subject in different languages will have noticed the lack of uniformity in the use of terms and the need for some measure of standardisation. As a first step in this direction a provisional glossary of terms has been compiled in six languages, and by circulating this repeatedly to experts in different countries for corrections and suggestions it is hoped in course of time to achieve an approach to finality.

What is perhaps a still more important undertaking is the effort to increase the amount of

authentic material available for research. This can only be done by inducing collectors to obtain wood samples from the trunks of the same trees from which herbarium material is taken. It should be our aim to build up wood collections comparable to our national herbaria; those that we have are hopelessly encumbered by commercial samples of timbers and specimens collected in all good faith but entirely without regard to the need of ensuring their true botanical authenticity. There can be no better example of the need for co-operative effort than the preliminary work necessary to establish on a sound basis the thorough investigation and successful utilisation of the timber resources of the overseas dominions of the British Empire.

Stellar Radial Velocities

By Dr. R. O. Redman

THERE has recently been published by the Lick Observatory a General Catalogue of the Radial Velocities of Stars, Nebulæ, and Clusters by Joseph Haines Moore.* This gives all radial velocities published up to January 1, 1932, and includes 6739 stars, 133 gaseous nebulæ, 18 globular clusters and 90 extra-galactic nebulæ. For some time a need has been felt for such a compilation, and after consultation with the members of the radial velocity commission of the International Astronomical Union, which includes practically all the workers active in this field, Dr. Moore undertook the task. Himself a radial velocity observer of considerable experience, he has carried out this work very thoroughly and the publication forms a compact collection of observational data of extremely great value.

It is very fitting that this catalogue should be issued by the Lick Observatory, which has played such a leading part during the past forty years in the measurement of radial velocities of stars and nebulæ. The first attack on the measurement of the Doppler shift in stellar spectra was made by Huggins in 1866, using visual methods, but the task proved difficult, and reasonably reliable results were not obtained until Keeler's work with the Lick 36-inch refractor about 1890. Even then velocities were obtained only with one or two of the brightest stars in the sky.

However, at about this same time, line of sight velocities were successfully measured at Potsdam by photography. The great superiority of the photographic method was quickly realised and soon extensive work was started, particularly by Campbell and his associates at the Lick Observatory. Observations have been accumulating with increasing rapidity ever since. As is well known, the results have been among the most valuable of astrophysical data and have found many applications, in the determination of masses in binary stars, in the study of variable stars, in stellar motions and the dynamics of the Milky Way system. Radial velocity technique has also contributed support to relativity theory in observations of Sirius B and to the theory of the expanding universe in recent observations of the spiral nebulæ.

The practical problem of radial velocity determination consists in the measurement of displacements of lines in an absorption spectrum formed by light from an extremely faint source. The unavoidable complications present in all astronomical observations, namely a rotating earth and an unsteady atmosphere of varying transparency, have also to be contended with. The average stellar velocity in the line of sight is around 15 or 20 km./sec., which corresponds in the ordinary photographic region of the spectrum to a Doppler shift of approximately one quarter of an angstrom.

The experience of the past thirty or forty years has indicated with little ambiguity the most desirable type of instrument to use. A telescope of large aperture is essential—36 in. is the least size with which any important amount of work is done at present—and, although refractors have in several cases given excellent service, it is generally considered that reflectors are more desirable. Their advantages lie in ease of construction, in their perfect achromatism, in their greater efficiency in the region of shorter wavelengths and in the long equivalent focal length which may be obtained without an inconveniently long telescope tube. The Cassegrain arrangement of mirrors, with a convex secondary reflecting the beam back through a hole in the centre of the primary, is undoubtedly the best.

The spectrograph is normally carried on the telescope, and since it may then be required to work in almost any position, it has to be constructed and mounted with special precautions against flexure or distortion of any kind. Prisms are usually employed since they are less wasteful of light than are diffraction gratings. One prism is most commonly used, although the number may be two or three for the brighter stars, and several interchangeable cameras of various focal lengths are usually available. In this way a fairly wide range of dispersions can be provided, varying perhaps from near 10 to around 100 angstroms per millimetre at Hγ (λ 4340) and suitable for use with stars of a wide range of apparent brightness. Since effectively the observing is done in the open air, the spectrograph should be enclosed in an insulating case and its temperature controlled by a thermostat. Exposure times vary enormously with magnitude and type of stars, with observing conditions and with the particular instrument used. Extensive radial velocity work is rarely carried out where more than one or two hours per photograph are required in fair weather. The

* Publications of the Lick Observatory, Volume 18, 1932.

resulting photographs are measured on special micrometer machines, the positions of the spectral lines being determined with reference to a comparison spectrum of the iron arc or some other convenient standard source.

Particular reference may be made to the work on extra-galactic nebulæ, the spectra of which almost without exception show displacements corresponding to large velocities of recession. The objects in question are generally extremely faint, and in addition their light is spread over an appreciable area of the sky, instead of being concentrated like that of a star. They are more difficult to observe than the diffuse and planetary nebulæ, since they have absorption, not emission, spectra. Pioneer work was done by V. M. Slipher at the Lowell Observatory, Flagstaff, but the more extensive recent measurements have been made at Mt. Wilson, where spectra of extremely small dispersion are taken with a special short focus camera lens working at f 0·6. The slit is used very wide and the exposures are sometimes very long, extending over several nights. In the photographs it is generally possible to distinguish only one or two of the strongest features of the spectrum, but the displacements, thanks to their great size, are usually determined well within ten per cent.

Reverting to more normal stellar work, the errors of measurement of radial velocities, as one might expect, vary a great deal according to the dispersion of the spectra and the nature of the spectrum lines. With a one prism instrument giving 25 or 30 A./mm. at Hγ, the probable error per plate is approximately 1 km./sec. in the case of a star with many sharp spectral lines, but with some spectra where the lines are few and nebulous, this error may easily exceed 5 km./sec. Systematic errors have in the past usually been evaluated by intercomparison of results from different observatories. Their average value is generally rather less than 1 km./sec. Now, however, as work is being pushed further to fainter apparent magnitudes, there is considerably less overlap than formerly between the work at one observatory and another, and standard stars are coming into use for the purpose of checking systematic errors. A list of such stars was published some years ago by the radial velocity commission of the International Astronomical Union and has proved very valuable. It is at present being revised and extended to fainter stars.

An inspection of Dr. Moore's catalogue gives some idea of the total progress made to date in this work. Thanks chiefly to the Lick Observatory, all stars have been adequately observed down to magnitude 5·51, but apart from this no group of stars has been completely observed over both northern and southern hemispheres. In the northern sky various groups of objects such as the Boss stars, the brighter dwarfs, the O to B5 stars down to magnitude 7·5, and certain classes of variables, have been observed, and further systematic work is being pushed forward, particularly at the Lick, Victoria and Mt. Wilson observatories. On the other hand, the southern sky below declination $-25°$, with the exception of the brighter stars just mentioned, remains practically untouched. Neglecting for the moment the fact that there are known to be many variable and peculiar stars of great interest in this region, knowledge of which would be very greatly advanced by radial velocity observations, this gap in our data is most serious in work on stellar motions. Until it is filled, observational studies of such questions as galactic rotation and certain other features of stellar movements must necessarily be incomplete.

Unfortunately, there seems to be no immediate certainty of a suitable telescope being established in the southern hemisphere for this purpose. At the recent meetings at Cambridge, Massachusetts, the radial velocity commission and later the general assembly of the International Astronomical Union, fully alive to the unsatisfactory nature of the present situation, passed a resolution asking that every effort be made to further any project aiming at the establishment and efficient working in the southern hemisphere of a large reflecting telescope for stellar spectroscopy and in particular for the determination of radial velocities. It seems unfortunate that some of the large sums of money devoted to several schemes at present on foot to build large instruments in the northern hemisphere, could not have been diverted towards filling this need in the southern sky.

Apart from this gap, which will have to be filled at some time, future work in radial velocities is likely to concentrate on refined observations of the brightest stars, on variables and peculiar objects, and on obtaining large numbers of velocities of fainter stars for statistical work. These last need not be of very great accuracy, although systematic errors will have to be carefully watched. There is in these three directions an almost unlimited field for large telescopes.

Obituary

MR. FRANK FINN

FRANK FINN, whose recent death, at sixty-four years of age, we regret to record, was an exhibitioner of Brasenose College, Oxford, and an excellent classical scholar. Whilst at Oxford he took a great interest in ornithology, both as an observer of birds and a systematic naturalist. He acquired a reputation amongst dealers and spent a great deal of his time in identifying collections of skins. This pursuit, unfortunately, occupied much of the time that he should have devoted to classics, with the result that his academic success by no means equalled his capacity. It may be said that this showed almost the leading defect in his character, which prevented him from being really successful in any of his undertakings. He

was always more interested in something which it was unnecessary to do at the time than in the immediate duty before him.

After taking his degree with honours in 'Greats', Mr. Finn went on an expedition to tropical Africa and spent a considerable time travelling, observing, and collecting. On his return he became assistant to Col. A. W. Alcock, who was then in charge of the Indian Museum. There also it was characteristic of him that he devoted more time to observing animals in the Zoological Gardens in Calcutta and its vicinity than to his official duties.

In 1903, Mr. Finn resigned his post and returned to England. The rest of his life was occupied by various minor appointments, none of which he cared to hold very long; by writing for the Press, and by writing books on natural history, the chief of which are: "Indian Sporting Birds", 1915; "How to Know the Indian Waders", 1906; "The World's Birds", 1908; "Game Birds of India and Asia", 1911; "Bird Behaviour", 1919; and with E. Kay Robinson, "Birds of Our Country". 2 Vols. 1922–23.

Mr. Finn had a most remarkable memory for facts, and there is no doubt that in his powers of observation and his real knowledge of birds and mammals, he had the making of a very great naturalist. For many years, however, he suffered from serious ill-health which made him irregular in his methods of working. He had, however, many delightful qualities and every naturalist who came intimately in contact with him had the highest possible appreciation of his knowledge and abilities.

WE regret to announce the following deaths:

Dr. Ernest Clarke, C.V.O., distinguished for his work in ophthalmic surgery, a manager and vice-president of the Royal Institution, on November 22, aged seventy-five years.

Mr. W. H. Patchell, consulting engineer, president of the Institution of Mechanical Engineers in 1924–25, on November 24, aged seventy years.

Mr. Charles M. Stuart, first headmaster (1888–1922) of St. Dunstan's College, Catford, who did much for the promotion of scientific method in education, on November 22, aged seventy-five years.

News and Views

Honour for Prof. Karl Pearson, F.R.S.

PROF. KARL PEARSON, of University College, London, has been awarded the Rudolf Virchow medal by the Berlin Gesellschaft für Anthropologie, Ethnologie und Urgeschichte. The award is made in recognition of Prof. Pearson's conspicuous services for the advancement of the study of human biology, and especially his pioneer work in the field of biometrics and his contributions to the study of eugenics, in which he has carried on and extended the work of the late Francis Galton. In conveying the announcement of the award, Prof. Eugen Fischer, president of the society, recalls the fact that up to the present the only recipients of the medal have been von der Steinen and Koch-Grünberg, the ethnologists; Olshausen and Heger, the archæologists; Toldt and Hans Virchow, anatomists; and lastly Erwin Baur, the geneticist. The value of the award is enhanced not only by its significance as a recognition of the international character of science, but also by the fact that on this, the first occasion on which the award has been made to a scientific worker outside the boundaries of Central European countries, the choice has fallen on one who is British. This, however, is not the only tribute which has been paid recently to the position in international scientific circles held by Prof. Pearson. The Sixth International Congress of Genetics, when assembled last summer in plenary session at Ithaca, New York, in conveying cordial greetings to Prof. Pearson and "best wishes for his health and long success and satisfaction in his scientific work", acknowledged the great indebtedness of the science of genetics to the statistical methods developed by him and now universally used.

To no one could these honours have fallen more appropriately. As Galton professor of eugenics in the University of London and as director of the Francis Galton Laboratory of National Eugenics, Prof. Pearson has attained a world-wide reputation for the originality and fertility of his application of statistical methods to the problems of biology and anthropology. His statistical methods have been developed in innumerable papers contributed to scientific periodicals and in a number of books, of which the "Grammar of Science" (1899) and "National Life from the Standpoint of Science" (1901) have exerted no inconsiderable influence on the development of scientific thought. These methods have been applied to the study of topics to which their adaptability would at one time have been inconceivable to any but the fertile genius of Francis Galton, whose life and letters were edited with discrimination and judgment by Prof. Pearson in three volumes (1914, 1924 and 1930). Yet notwithstanding the range and quality of his output, the great achievement of his fifty years teaching and work in London has been his success in inspiring and directing the work of others, for the most part his own pupils, who with him have contributed to the great advance in the exact scientific study of man and his heredity during the last generation. Prof. Pearson's success in this direction has been conspicuous in his editorship of *Biometrika*, a periodical for the statistical study of biological problems, which was founded by himself, the late W. F. R. Weldon and Sir Francis Galton. Happily, when Prof. Pearson retires from active teaching, as he proposes to do at the end of the current session, he will retain the editorship of this periodical.

The Furthest Depths of Space

THE theory of the expanding universe, which has lately attracted so much attention, formed the principal topic of Sir James Jeans's remarks in the Henry Sidgwick memorial lecture for 1932, which was given at Newnham College, Cambridge, on November 26, under the title "The Furthest Depths of Space". In a brief survey, Sir James introduced his listeners to the universe as we know it to-day, beginning with the naked-eye stars, then passing to the Milky Way system and from there to the extra-galactic nebulæ. These, in themselves objects of great importance, acquire additional interest as straws floating in the stream of space, showing how its currents are flowing. This space is curved, with a texture varying from the local irregularities which cause the electron to twist about in an electric or magnetic field, or the planets to move in curved orbits around the sun, to a bigger, coarser texture which makes space curve round on itself and finally close up. The state of curvature is not quite that of a universe in equilibrium as first conceived by Einstein, for later investigators, Friedmann, Lemaître and others have shown that such an equilibrium would be unstable. Space would immediately commence expanding or contracting with ever-increasing speed. We do not know what was the initial impulse which began the expansion. It may have been the starting of condensation in the primeval gas of which the universe is generally supposed to have consisted, but the suggestion, Sir James thinks, has not yet been strictly proved.

Expansion of the Universe

THE expansion of the universe expected by theory has been strikingly confirmed by radial velocity observations of the spiral nebulæ, which, we may remark, is discussed by Dr. R. O. Redman elsewhere in this issue (p. 836), but a serious difficulty immediately arises. The expansion is so fast that it cannot easily be reconciled with an evolutionary age of the universe greater than about 10^{10} years. Yet all other astronomical evidence requires an age of 10^{12} or 10^{13} years. The rate of expansion has been deduced theoretically by Eddington, who finds remarkable agreement with observation, at least so far as order of magnitude is concerned. If he can put his very daring calculations in a form which will command the general assent of mathematicians, they will provide a very strong confirmation of the whole theory of the expanding universe. Two other recent investigations have tried, in very different ways, to dispose altogether of the cosmical constant, the quantity which on Einstein's original theory fixed the amount of the large-scale curvature of the universe. Milne has supposed that the nebulæ were formerly bunched together in a quite small region of space and endowed with motions which have produced both their present distances and their present velocities. This does not solve the age difficulty and Sir James feels also that the simplicity of this explanation has been achieved by assuming practically all that is to be explained. On the other hand, the recent work of Einstein and de Sitter suggests that really we know no reason which makes space have any inherent curvature. There seems to be a possibility that the universe is undergoing a series of expansions and contractions, in which case we have all the time we want for its evolution. This appears to Sir James to be the only possibility at present in the field which is not exceedingly difficult to reconcile with our general knowledge of astronomy.

Crete and Mainland Greece

FURTHER evidence of the influence of Minoan Crete on the mainland of Greece after the fall of the Palace of Knossos was brought forward by Sir Arthur Evans in his lecture before the Hellenic Society on November 22. It has been derived from a number of inscriptions painted on vases discovered in a cellar by Prof. A. D. Keramopoulos, while excavating the Cadmeia of Thebes. These Sir Arthur has been allowed to examine and copy, and their publication has been reserved for him, by the Greek Archæological Society. The script, Sir Arthur said, answers in an overwhelming degree to that current in the latest phase of the Palace of Knossos as represented in more than 1,400 inscribed tablets. Out of about sixty signs gathered from the Minoan documents, no less than forty occur in the twenty-eight inscriptions from Thebes. In two instances the Theban inscriptions show the same signs as occur in the list of personal names in the inscription found at Knossos in 1902. Further, a comparison with the fragmentary inscriptions found on vases at Tiryns by the German excavators, and a few from Mycenæ, establish the identity of their script with that of Thebes. They also include a Knossian personal name. It may therefore be regarded as proved, Sir Arthur concluded, that in Mycenæan Greece of the fourteenth century B.C., the urban population spoke a language implanted from Crete, a language which in that island can be traced back to the third millennium B.C., and, if personal names count for anything, can be linked to the Carian races on the Anatolian side.

Marine Biology of the University of Sydney

DURING the past three years a scheme of oceanographic investigation has been initiated and conducted from the Department of Zoology of the University of Sydney, under the direction of Prof. William J. Dakin. The work commenced with an examination of the plankton and hydrographical conditions prevailing in the ocean waters off the entrance to Sydney Harbour. This is the first long-continued investigation of the plankton, that is, a study of the seasonal changes over a period greater than a year, to be made in Australian waters. In fact, little or nothing has been published regarding the seasonal changes in the plankton at any one station in the temperate waters of the southern hemisphere. The work has been greatly facilitated during the past year and a half by the acquirement of a small auxiliary yacht of about 12 tons (which has proved more suitable than a launch for ocean waters), and by the erection

of a Marine Biological Station at the entrance to Port Jackson, both being the property of the University. This biological station is at present the only one permanently equipped and in continuous use on the Australian coast.

Seasonal Plankton Rhythm

AT the recent meeting of the Australian and New Zealand Association for the Advancement of Science, it was stated by Prof. Dakin that plankton studies in New South Wales waters had shown a distinct diatom maximum in the spring, followed by a smaller maximum in the autumn. These conditions presented an interesting and close parallel with those so well known in the temperate waters of Europe. In further agreement a scarcity of plankton is recorded during the winter months and the planktonic Crustacea—*Copepoda* and *Cladocera*—rise to maxima in the early summer following the diatom and dinoflagellate maxima. The variations in the abundance of plankton during the year do not seem to be anything like so great as in the Irish Sea or English Channel, and it would almost appear as if the phosphate and nitrate concentrations in the sea water were also more uniform. The study of the relation between the seasonal rhythm of the plankton and changes in the physico-chemical environment is to be continued, whilst particular attention will be paid to the occurrence of fish eggs and larvæ.

Fisheries of the Philippines

THREE fully illustrated accounts of various Philippine fisheries are published in the July number of the *Philippine Journal of Science*, No. 3, vol. 48, 1932: "The Japanese Beam Trawl used in Philippine Waters", by Augustin F. Urnali; "The Fisheries of Lake Sampaloc, San Pablo Laguna Province, Luzon", by Florencio Talavera; and "Fishing Appliances of Panay, Negros and Cebu", by Florencio Talavera and Heraclio R. Montalban. Fishes of many kinds, shrimps and other Crustacea, molluscs and holothurians are all important commercially in the Philippines. In some parts the fishing is deteriorating from over-fishing, lack of attention, or from physical causes. New methods and restrictions are recommended by the different writers. The Japanese beam trawl is at present used only by Japanese, in their own boats, manned by their own men. It is apparently no more destructive than the other methods of fishing, and its use is advised for the native fishermen. Lake Sampalac, the largest of the nine crater lakes in the San Pablo Valley, was an important fishing centre before its height was lessened by approximately 10 metres. Now, partly from this alteration and partly from other causes which are investigated fully by Dr. Talavera, of the Division of Fisheries, Bureau of Science, Manila, the fishes are certainly decreasing, and legislative measures together with restocking are suggested. The shrimps in this lake appear to be inexhaustible. The multiplicity of terms used in the local fisheries and the names for the various appliances are astonishing, but these are all carefully explained and illustrated in the third paper.

Oceanography in Spain

IN June 1933 the first Iberian-American Oceanographical Conference will be held in Madrid. The Council, under the presidency of Prof. D. Odon de Buen of Madrid, was instituted in 1929 in order to facilitate co-operation between the Iberian Peninsula and parts of America, the countries involved being Spain, Argentina, Costa Rica, Ecuador, Salvador, Guatemala, Mexico, Panama, Peru, Dominican Republic, and Uruguay. The publications of the Council consist of a review (*Revista del Consejo Oceanografico Ibero-Americano*), which has been in existence for three years and contains many interesting short papers, and the memoirs (*Memorias del Consejo Oceanografico Ibero-Americano*), eleven numbers of which have been published, each containing one long paper. No. 9, by Prof. Rafael de Buen, deals with all the activities connected with the Spanish Institute of Oceanography, which was founded in 1914 to unite in one centre the coastal marine laboratories already in existence, situated in Palma de Mallorca, Malaga, and Santander. All these are now connected with the main oceanographical laboratories in Madrid, where all investigations are centralised, the director being Prof. Odon de Buen. Various expeditions have been undertaken, mainly in the Mediterranean, and in 1924 Spain joined the International Council for the Exploration of the Sea, among other things working out certain hydrographical problems round Cape Finisterre and studying the biology of the sardine and other fishes, including the hake, tunny, and bonito.

Tasmanian Rock Carvings

A DISCUSSION of the origin of certain alleged rock-engravings at Mersey Bluff, Devonport, Tasmania, appears in the *Papers and Proceedings of the Royal Society of Tasmania* for 1931. In its general bearing the paper is of considerable interest to archæologists and students of primitive art. Mr. A. L. Meston, who argues for the authenticity of the carvings, has examined and describes a number of them. He claims that he has identified representations of fish, coiled snakes, a bird's head, *Haliotis* shells, cup-and-rings, and concentric circles. The carvings are on horizontal surfaces of a hard diabase, and are not scratched but are incised, as if by a hard implement, such as a quartzite tool, impelled by a hammer. The existence of Tasmanian aboriginal carvings and drawings has been doubted, notably by the late H. Ling Roth; but Mr. Meston states that these examples have been accepted by those acquainted with primitive rock-carvings elsewhere. The case against the authenticity of these carvings is taken up by Mr. E. O. G. Scott, of the Queen Victoria Museum, Launceston, who has made an extensive and detailed report on the subject to the Museum Committee. A brief outline of his arguments appears in the *Proceedings*, pending decision as to publication in full. His conclusion is that the 75 rock-markings claimed by Mr. Meston to be carvings are not of aboriginal origin, but are items in an extensive series of natural erosions which have in general occurred along lines

of inherent pneumatological weakness in the Mesozoic region. He also suggests that rock-lichens have played a not unimportant part in the process of erosion of the grooves, and in some instances may have initiated them.

Mammoth Remains in New Jersey

IT is announced by the Academy of Natural Sciences of Philadelphia that five teeth and several fragments of bone of the mammoth (*E. primigenius*) have been discovered near Blackwood, New Jersey, twelve miles south-east of Philadelphia. The discovery was made in the course of work on the golf course of the Hidden Lake Country Club, and the remains were identified by Mr. Edgar B. Howard of the Academy's Department of Zoology. The teeth were found at a depth of 4 ft. within a small radius of what was once the bed of a fairly wide creek, now the bank of a streamlet. Each of the five teeth is fairly whole and one clearly shows the roots, of the size of a man's finger. In size the teeth range from 3 in. × 5 in. × 7 in. to 4 in. × 5½ in. × 9 in. and in weight from 3½ to 6¾ lb. each. The thin enamel ridges which traverse the chewing surface are still clearly visible. This constitutes the most impressive find of mammoth remains yet made in the eastern United States. Previously no more than a single tooth had been found in any one locality. Previous finds were at Trenton and North Plainfield, New Jersey, and five in Pennsylvania. In the Pleistocene epoch the mammoth had a distribution in North America ranging from Alaska, through British Columbia and the northern United States to the Atlantic, being a migrant by way of the Asiatic-Alaskan land-bridge from Siberia, where frozen specimens, complete with flesh, hide and wool, have been found in recent times. The fossils from Blackwood, with the tooth from Chadd's Ford, are now on exhibition in the museum of the Academy of Natural Sciences of Philadelphia.

Botany Collections at the Natural History Museum

THE Godman Trustees have presented to the Department of Botany of the Natural History Museum a collection of about six hundred plants made by Mr. R. C. N. Young in north-east Angola (Lunda). The Department is particularly rich in Angolan plants having valuable collections from F. Welwitsch and J. Gossweiler. The present set of plants is of considerable interest as it is from an area so far botanically unknown. Three octavo volumes of British plants have been presented by Miss Jackson. The interest in these is bibliographical, as there is a printed title page giving publisher's name and date (1847); there is also a printed preface. The title reads "Specimen Flora or British Botany exemplified by Plants from a Collector's Cabinet". The plants were "arranged by the author of 'The Pictorial Flora'" [Mary Ann Jackson].

Birds of Northumberland

FOR the third time the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne has published a catalogue of the birds of the district—P. J. Selby in 1831, John Hancock in 1874, and now, as a worthy successor, appears George Bolam's list of 1932. It appears as a special part (vol. 8) of the *Transactions* of the Society, and in order to avoid undue repetition, it takes as its datum line Mr. Bolam's own list of 1912, in his "Birds of Northumberland and the Eastern Borders". Hancock's catalogue included 255 birds for Northumberland, by 1912 the number had risen to 282, now the number well exceeds 300, and this largely because of the finer analysis of species and racial forms. Of course quite a considerable number of the birds in this or any other local list are no more than accidental visitors, the presence of which really means very little from a local point of view. Here, for example, the smew, with four records, takes more space than the swallow, martin, and sand-martin all added together; and yet fluctuations in the numbers of these summer visitors would be more worth recording than the odd occurrences of the winter duck. From a scientific point of view, the day of usefulness of the county list, unless it becomes an intimate and detailed chronicle of local changes and fluctuations, is past, and we venture to think that the third Northumberland catalogue of birds will be the last, notwithstanding its particular value and appeal to the people of the county itself.

Pest Control and Wild Animal Life

IN many parts of the United States of America the destruction of agricultural pests has become an intensified and highly specialised warfare organised by State departments. But it has scarcely been realised that the destruction is apt to reach far beyond the pests at which it is aimed. This would appear to be true particularly of large scale use of thallium and strychnine baits, the former of which is preferred at most seasons and in most areas because it makes 'better kills' than other types of poison. Dr. Jean M. Linsdale has collected further facts concerning losses to wild life in California from these sources, and summarises the reports of 285 observers who have found dead mammals and birds (other, of course, than squirrels and coyotes) unquestionably killed during pest control campaigns (*Condor*, vol. 34, p. 121; 1932). The list occupies 13 pages of the magazine, and it must be remembered that it covers, as a rule, only conspicuous species—many others must have passed unnoticed or unidentified. The author is of opinion that the accelerated development of pest control methods and their uninterrupted practice could so change the native bird life of California within a few seasons that all previous activities for its preservation would be nullified. The publication of these facts, however, should induce the authorities to reconsider their methods of pest destruction.

The Cinematograph as an Aid to Histology

A NEW reconstructional technique is put forward by Messrs. Peacock and Price in the September issue of the *Journal of the Royal Microscopical Society*. Successive photographs of the sections in a uniform series are taken on standard cinema film and after-

wards projected. It is found that an apparently continuous flow of the image on the screen can be obtained if about seven frames are exposed for each section. The camera is mounted between the microscope and a paper screen, sharp focus of the former being secured by exposing a number of frames at recorded settings of the fine adjustment; the camera is then swung out of the optical axis and the image brought to a sharp focus on the screen by means of a supplementary lens. The screen is now used to secure orientation and focus for each successive section, the camera being swung into the optical axis when a suitable adjustment has been obtained. Though much difficulty is at present occasioned through the distortion of successive sections during mounting, the new technique will prove a considerable aid both in teaching and in research.

Development of International Law

THE *New Commonwealth* (monthly, published at Mowbray House, Norfolk Street, Strand, W.C.2., price 6*d*.), the first issue of which has recently appeared, is the organ of a new international society formed to advocate the establishment of a world system of law and order. If "the common sense of all" is to "hold a fretful realm in awe", effective provision must be made for the administration of international justice, and this can be achieved only, in the new society's view, by establishing: (1) an international tribunal, to deal with all disputes threatening the peace of the world which do not at present come within the purview of the Permanent Court of International Justice; and (2) an international police force as the sanction of international law and a guarantee of security against aggression. On these two objectives the society proposes to focus and interest public opinion. As Sir Arthur Salter says in a letter to the editor, the times are dangerous and moral suasion alone cannot be relied upon to defeat the material forces of the world if these are all allowed to be harnessed to policies of evil. In an open letter signed by Norman Angell, Lord Cecil of Chelwood, the Archbishop of York, Sir Oliver Lodge, Prof. Gilbert Murray and sixteen other eminent citizens of nine of the principal countries of the world, the *New Commonwealth* is commended to all those who are interested in the development of the reign of law.

Production and Employment

IN a pamphlet entitled "The Prevention of Future Economic World Crises", Herr Robert Bosch of the Bosch Company, Stuttgart, points out that the present world-wide business depression differs radically from previous ones which were caused principally, if not exclusively, by a preceding unhealthy boom. He argues that the troubles of the present depression are not due to over-efficiency of production methods as commonly supposed but rather to the inefficiency and backwardness of non-technical branches of the world's activities. Foreign relations are handicapped by antiquated political and mercantilist conceptions leading to armaments and tariffs while national prosperity is handicapped by wasteful and inefficient administration and distribution and by antagonism between different groups of society. It is necessary to write off superfluous plant capacity so that the remaining factories may be run efficiently. Herr Bosch visualises a reduction of the yearly working time to 1800 hours or less in place of the present 2400 hours so as to guarantee some employment at fair compensation to every worker, but he recommends that the rigid eight-hour day should be replaced by more flexible arrangements so as to provide the maximum economy in the operation of particular factories.

Scientific Treatment of Delinquency

A NEW era in the investigation and treatment of crime was outlined at an inaugural meeting of the 'Institute for Scientific Treatment of Delinquency' held at University College, London, on November 29. The chairman, Dr. Edward Glover, pointed out that existing criminal and penal codes differ in no essential respect from the behaviouristic codes spontaneously evolved by two-year old children. He emphasised the urgent need for centralisation and co-ordination of effort at present made by small independent organisations. In his opinion any research on the subject should be conducted in an attitude of complete detachment from preconceived views as to desirability. The need for such an Institute was emphasised by a number of speakers. Amongst these, Lord Feversham dealt with the problem from the point of view of adequate probationary handling. Drs. Hadfield, Rees and Emanuel Miller recounted medico-psychological experience of handling delinquents at various clinics and welfare centres. The points of view of general science, ethics and politics were presented by Prof. Winifred Cullis, Canon Donaldson and W. J. Brown respectively. The Institute's immediate plans for co-ordination research, treatment and technical instruction were then outlined by Dr. Glover. It is hoped that within a short time a reasoned report on the present system of criminological work may be put before the various Government departments concerned. All communications should be addressed to the honorary secretary of the Institute, 56 Grosvenor Street, London, W.1.

The Study of an Oilfield

SOME observations on this subject were made by Mr. J. W. Weil in a paper read before the Institution of Petroleum Technologists on October 11. The paper was perhaps timely as representing the case for petroleum geology taking its logical place in the systematic scheme of oil production. Latterly there has been a decided tendency to interpret underground reservoir conditions—even geological data—on the basis of such functions as flowing pressures, oil and gas measurements, gas-oil ratios and other physical determinations which have been advanced as part of the standard technique of production engineering. The author pleads, and rightly so, for a thorough geological investigation as precedent to oilfield development and, in this connexion, he stresses the necessity of adequate study of stratigraphy, structure, factors influencing the accumula-

tion of oil and gas, data necessary for correlation of horizons and the construction of stratigraphical and production maps. While there is clearly nothing strikingly new in this communication, the paper will have done good if it directs the attention of those primarily concerned to the fact that, while geology may be substantially aided by the applications of its contact sciences, its principles as governing the understanding of sub-surface oil pools can never be superseded.

Mining Research at Birmingham

THE Executive Board of Mining Research of the University of Birmingham has issued a report on the work of the Mining Research Laboratory for the year 1931. The Laboratory receives grants from the British Colliery Owners' Research Association, the Department of Scientific and Industrial Research, and the Miners' Welfare Fund, which supports work in connexion with the problems of safety in mines. The report bears witness to the wide range of sciences—physics, chemistry, geology, and physiology—which are focused upon the problems of the coal industry. Much attention continues to be given to spontaneous combustion, as underground heatings are a prolific source of danger and accident. For some years the Laboratory has examined the hydrogenation of coal. While this problem has come to be regarded as technically solved, economic success seems to be so remote that the work has been suspended. Attention is being turned to problems connected with the use of compressed gas for road transport.

Social Conditions of Miners in India

THE September part of the most recent volume of the *Transactions of the Mining and Geological Institute of India* contains an important paper by Mr. R. R. Simpson, chief inspector of mines in India, upon the social conditions of miners in India, together with an animated discussion upon it. The paper is particularly interesting in itself, and all the more so because it discusses in detail a number of the very numerous recommendations made by the Royal Commission sent out in 1929 to inquire into Indian labour conditions, which made its report in 1931. The members who discussed the paper expressed varying views, and evidently looked upon Mr. Simpson's paper as a peg on which to hang the discussion of the recommendations of the Royal Commission. The paper and discussion occupy considerably more than fifty pages, and, therefore, do not lend themselves to any ready abstract, but both are well worth careful study on the part of those who wish to understand thoroughly Indian labour conditions.

Exhibition of Chemical Plant at Cologne

"ACHEMA VII", the seventh exhibition of chemical plant and equipment organised by the Deutsche Gesellschaft für chemisches Apparatewesen ("Dechema"), is to be held at Cologne on June 2–11, 1933. Similar exhibitions have been held since 1920 in Hanover, Stuttgart, Hamburg, Nürnberg, Essen, and Frankfurt-am-Main. The exhibition next year will be associated with meetings of the Verein deutscher Chemiker and other technological associations, in particular the Deutsche Brennkrafttechnische Gesellschaft and the Deutsche Kautschukgesellschaft, and with a Rubber Exhibition which will form the summer exhibition of the city of Cologne and will remain open until October 1933. The three principal halls around the congress hall in the Rheinpark will contain examples of acid-proof stoneware and other ceramic products, technical instruments for measurement and control, non-metallic and non-ferrous plant, laboratory apparatus and instruments, and machinery, with examples of complete plant and processes, raw materials and products. The rubber section will illustrate historically the development of methods for the production of rubber and of its industrial applications. An exhibition of such character will necessarily attract international interest, and nowhere more than in countries where chemical industries and the manufacture of chemical plant have reached a high standard of attainment. Particulars of the exhibition can be obtained from "Dechema", Seelze, near Hanover.

Mosquito Control

UNDER the title of "A Mosquito Summary", Mr. John F. Marshall, director of the British Mosquito Control Institute, Hayling Island, Hants., has recently issued an illustrated pamphlet of an essentially practical character. In a short and concise manner it explains how to recognise a mosquito, how such insects breed and how to distinguish anophelines from culicines in all stages of life. The manner in which mosquitoes carry disease and methods of controlling these insects are also summarised. The pamphlet, which is obtainable from the Institute (price 9*d*.) should prove useful to health officers and others concerned with mosquito eradication.

Dairy Research

WE have received the annual report for the year ended July 31, 1931, of the National Institute for Research in Dairying at the University of Reading. In common with other Institutions, a restricted income has necessitated a percentage reduction upon all salaries and wages and a curtailment of research work, the Government's grants for 1931–32 being less than previously by nearly £2,000. An account is given of the work of the various departments, with brief abstracts of scientific contributions made by the staff. An obituary notice, with portrait, of the late director, Dr. Stenhouse Williams, is included.

Bishop's Ring and the Andean Eruption

MR. J. FRASER PATERSON, writing from Broken Hill, Australia, says :—"The rare phenomenon known as Bishop's ring was visible in the western sky at 5 P.M. on Saturday, July 23. This date is about ten and a half weeks after the Andean eruptions. The colour of the ring was sepia."

Announcements

PROF. DAVIDSON BLACK, professor of anatomy in the Union Medical College, Peking, will deliver the Croonian lecture of the Royal Society on December 8. The title of Prof. Black's lecture will be "The Discovery of *Sinanthropus*".

UNDER the Order in Council dated February 6, 1928, the Lord President of the Council has appointed Dr. T. Franklin Sibly, Vice-Chancellor of the University of Reading, to be a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

THE following officers and new members of council of the London Mathematical Society have been elected for the session 1932-33: *President:* Prof. A. C. Dixon; *Vice-Presidents:* Prof. S. Chapman, Prof. H. Levy, Mr. T. L. Wren; *Treasurer:* Dr. A. E. Western; *Librarian:* Prof. H. Hilton; *Secretaries:* Prof. G. N. Watson, Mr. F. P. White; *New Members of the Council:* Prof. J. C. Burkill, Mr. W. L. Ferrar, Prof. E. A. Milne, Prof. G. F. J. Temple, Prof. E. C. Titchmarsh.

A CONFERENCE is being called by the Building Research Station of the Department of Scientific and Industrial Research to consider proposals for the establishment of a fire testing station for the building industry. The conference will be held at the Institution of Civil Engineers on Wednesday, December 7, at 11 A.M., under the chairmanship of Sir Clement Hindley. Firms and bodies which have not received invitations to the conference direct, but wish to send representatives, should communicate with the Director, Building Research Station, Garston, Watford, Herts.

THE annual Congress of the British Institute of Radiology will be held at the Central Hall, Westminster, on December 7-9, under the presidency of Prof. F. L. Hopwood. The Congress will be officially opened by Sir George Newman on December 7. In connexion with the Congress an exhibition of X-ray apparatus will be organised by the British X-ray industry. The thirteenth Mackenzie Davidson memorial lecture will be delivered by Dr. J. Chadwick on "The Neutron" and the fifteenth Sylvanus Thompson memorial lecture by the Right Hon. Viscount Lee of Fareham on "Radium as a Therapeutic Agent—The Case for National Control". The papers will be divided into medical, and physical and technical sessions.

THE attention of biologists may be directed to the Peking Natural History Society's *Bulletin* now in its seventh volume. This journal is doing good work in publishing illustrated papers on the fauna, flora, general biology, etc., of China. Its trend is largely zoological and through the medium of its pages additions to the fauna of China are frequently made known. The majority of the contributions are written in English by Chinese investigators, while there are occasional papers by European and other specialists. The editor of the *Bulletin*, to whom contributions and requests for exchange should be addressed, is Dr. Chenfu F. Wu, Department of Biology, Yenching University, Peiping, China.

THE Ministry of Agriculture and Fisheries has issued new editions of three advisory leaflets, dealing respectively with "Cleanliness in Dairying" (No. 140), detailing the causes and prevention of contamination of milk, "Caerphilly Cheese" (No. 141) and "Cheshire Cheese" (No. 142), the last two describing the manufacture of these cheeses. The leaflets cost 1*d*. each, and are published by H.M. Stationery Office.

WE have received from Messrs. Watson and Sons (Electro-Medical) Ltd., 43 Parker Street, Kingsway, London, W.C.2, a copy of a booklet and folder describing a new X-ray outfit for dental work, the "Sunic" Mark III shockproof unit, which, as its name implies, is claimed to afford complete protection from electrical as well as X-ray dangers. The booklet also gives a simple account of X-rays and their production.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A temporary mistress to teach principally arithmetic and geography at the Aston Junior Commercial School—The Chief Education Officer, Higher Education Department, Education Office, Margaret Street, Birmingham (Dec. 5). A civilian photographic officer at the Royal Air Force School of Photography, Farnborough—The Air Ministry, Adastral House, Kingsway, W.C.2 (Dec. 10). A temporary demonstrator in the Department of Biochemistry at the University of Liverpool—The Johnston Professor of Biochemistry, The University, Liverpool (Dec. 12). An assistant director of examinations in the Civil Service Commission—The Secretary to the Civil Service Commissioners, 6, Burlington Gardens, London, W.1 (Dec. 31). Examiners for scholarship and staff examinations of the London County Council, in scientific and other subjects—The Education Officer (G.P.1), County Hall, Westminster Bridge, London, S.E.1 (Jan. 2). A cartographer in the Hydrographic Department of the Admiralty—The Secretary, Civil Service Commission, Burlington Gardens, London, W.1 (Jan. 12). A Hope professor of zoology (with special reference to entomology) at the University of Oxford—The Registrar, University Registry, Oxford (Jan. 21). A technical assistant for the Public Health Laboratory at Salisbury, Southern Rhodesia—The Official Secretary to the High Commissioner for Southern Rhodesia, Crown House, Aldwych, London, W.C.2. A professor of horticulture at the University of Reading—The Registrar. An assistant lecturer in the Department of Physics at the Battersea Polytechnic, London, S.W.11—The Principal.

ERRATA.—In NATURE for October 29, p. 646, column 2, line 10, for "Sir Robert Boyce" read "Sir Rubert Boyce". In NATURE for November 19, p. 780, Research Item entitled "New Thermophilic Organisms", for "Bax" read "Dax" throughout.

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Redwoods of California

As one who once lived in the Redwood country, may I be allowed to thank the Master of Downing for his vivid pen picture in NATURE of November 12 of those inspiring monuments of the past, the Californian Redwoods ?

A few years ago, when camped in a Redwood grove, I was sleeping at night on the stump of a huge tree, felled perhaps in the early days of settlement. A ring of young coppice probably not less than 100 ft. high, growing out of the stump, formed a charming screen, among the branches of which the blue jays chattered and the Californian thrush poured out his cheerful evensong. Looking upward as we lay in bed, the stars could be seen twinkling through the openings of a sky-pattern akin to that shown in Dr. Cannon's excellent photograph. But at intervals of a few nights, the sky would be enveloped in a cold, grey fog; this condensed in the foliage of the tall spires and fell in a shower so heavy and continuous that unless our beds had been covered with waterproof they would have been wet through.

The ground beneath the Redwood is normally clothed with a layer of decaying foliage three to five inches, and sometimes even a foot, in depth; this is composed chiefly of Redwood leaves still attached to the branchlets on which they grew, for *Sequoia sempervirens* sheds its branchlets, though unlike the related swamp cypress (*Taxodium*) or the larch (*Larix*) it does not become leafless at any season.

An examination of the layer of dead leaves showed that although it was the 'dry' season of the year, the layer was wet through by the fog-drip from the branches above; into this spongy mass the Redwood had developed a dense system of rootlets, many being obviously young and in vigorous growth, some of them definitely growing upwards from the horizontal roots into the mass of humus above; doubtless the tree was drawing therefrom a supply of moisture and of plant food.

This constant renewal of food supply and moisture near to the base of the trunk, and the ability to renew, as it were, its root system at close range, may have something to do with the remarkable longevity of the tree. They explain, also, how the sea-fog compensates for lack of rainfall in the long, hot, rainless summer of California. But they suggest a serious menace to the continued existence of these magnificent relics of a former flora, in the treatment they are receiving—or were then receiving—at the hand of man. With a commendable desire to prevent forest fires, it was customary for the custodians of public camping grounds in the National, State, or County groves, to sweep the ground beneath the Redwoods quite clear of dead leaves. As these surface-rooting trees appear to depend for their water supply during a not inconsiderable part of the year on the moisture stored in the layer of decomposing foliage, it is probable that the sweeping bare, and subsequent consolidation, of the soil, checks the development of the superficial system of new roots, and causes too rapid evaporation of the much-needed summer moisture, from the soil surface. Though in some years the sea-fogs may continue for weeks at a time, they are often discontinuous, lasting about three days together, separated by more or less equal spells of hot, dry weather with almost cloudless skies, resulting in intense evaporation of moisture from a hard, bare, soil surface, though with comparatively little loss from a loose spongy mulch.

These facts explain the limitation of the Redwood to that narrow belt (averaging about twenty miles in width), which is watered by sea-fog in the rainless season, just as the evergreen rain-forest of Central and South Africa is limited to the 'mist-belt' of the eastern mountain chain. They may explain, also, the behaviour of the Redwood in certain parts of England, where it often has a shabby, unhealthy appearance though in other localities it is vigorous and apparently quite at home with its environment. In my garden there are both a young Redwood and a young "Big Tree" (*S. gigantea*); each has developed a set of rootlets near the soil surface. Noticing, last summer, that both trees showed signs of check in growth and some die-back of foliage, the Santa Cruz observations came to my mind, and treatment with a thick mulch of rotting grass and leaves (left on throughout the summer and renewed in winter) was tried; the beneficial effect was quickly noticeable. Late last spring the gardener, when tidying up, cleared the mulch from the Sequoias; during a warm dry period in early summer the trees again showed signs of suffering; the prompt application of a fresh mulch had almost immediate effect, followed by a steady growth of new wood equalling that of trees of the same age in their native haunts.

From these observations it would seem likely that in the drier parts of England, on gravelly or sandy soils, the Redwood would benefit from a mulch of leaves or rotting grass, especially during the drier summer months, and that this treatment might be applied with advantage to old-established trees as well as to young ones. If this surface-rooting habit is of regular occurrence in the species, such a mulch would afford protection to the roots against frost also. In fact, the desirability of maintaining a constant mulch under Sequoias seems to be indicated.

Heterogony and the Chemical Ground-Plan of Animal Growth

IN 1924 in this journal, Huxley[1] first considered the relation between the growth of parts in a living organism, when the parts increase or decrease in relative size. The equation

$$\log y = \log b + k \log x$$

describes the process, where y is the size of the part, x the size of the whole, and b and k are constants (the former giving the fraction of x which y occupies when x is unity, and the latter the ratio of the growth-rate of the part to the growth-rate of the whole). Thus on a double logarithmic grid, straight lines are obtained, the slope of which is determined by the constant k, and the absolute position of which relative to the axis values, by the constant b. Since Huxley's first paper, this simple relation has been abundantly verified for morphological magnitudes in a large number of

animals, vertebrate and invertebrate, as described in his recent book.[2]

It seems likely, however, that the value of these considerations will be found to be just as great for the biochemist as it has been for the anatomist and the zoologist. I have recently undertaken a study (to be published *in extenso* in the *Bulletin de la Société Philomathique de Paris*) of the chemical heterogony of developing embryos, and have extended it to include a number of sets of data covering the whole range of the life cycle in certain animals. For the development of an embryo, the chick, for example, the plotting of chemical entity against chemical totality (such as non-protein nitrogen against dry or wet weight) on the double logarithmic scale, gives almost without exception a straight line. In certain cases, the data seem to demand representation by two or even three successive straight lines, periods of positive or negative heterogony being followed by periods of isogony, or vice versa. It is not, however, upon these critical points that emphasis should, it seems to me, be placed, for closer statistical analysis or the availability of more accurate data, may show them to be artifacts. What does seem important is that in many cases, the slope of the straight line for a given substance or group of substances, is identical or very similar in widely different organisms. Thus in Fig. 1 the total ash is shown plotted on a double logarithmic grid against the dry weight for the embryos of chick, cephalopod, and some selachian fishes. In spite of the great differences in absolute weights and times, the heterogony is the same ($k=0 \cdot 89$ for the chick, $0 \cdot 86$ for *Sepia*, and $0 \cdot 91$ for the selachian fishes). Fig. 2 shows the fat of the chick embryo and the mealworm larva plotted in the same way. Again, the heterogony is the same ($k=1 \cdot 06$ for the chick, $1 \cdot 07$ for the mealworm).

This similarity of chemical development between different animals appears in numerous other instances: (1) water content of mammals, reptiles, birds, amphibians, fishes, cephalopods and arthropods throughout the life cycle, (2) nuclein content of chick and mammals, (3) dry substance of various mammalian brains, (4) proteins, phosphatides, cerebrosides, sulphatides, cholesterol, and extractives, of the brains of rat and man, (5) calcium in chick and mammals. The evidence on which these instances are based will be found in the paper referred to above.

In plotting chemical magnitudes heterogonically we 'short-circuit' time. In comparing the heterogonic plots of the same constituent of different organisms we abstract (*a*) from the morphological form, (*b*) from the nutritional factors, (*c*) from the absolute values of the magnitudes, (*d*) from the time taken to perform the work shown on the plot. We have nothing left but a system of relations or ratios, which may be the same in all animals, and seems certainly to be the same in many animals—in a word, a fundamental chemical plan of animal growth. Just as D'Arcy Thompson[3] could transform one actually existing morphological shape into another by systematic deformations of Cartesian co-ordinates, so the chemical ground-plan must be thought of as deformable in space-time. It is probable that the essential processes of growth proceed in all animals, whatever their form and size, according to a definite plan recognisable in the chemical constitution of the organism at any given stage of its life history.

Radioactivity of Samarium

THE discovery that the radioactivity of potassium is due to a minor isotopic constituent, suggests the idea that other common elements may also have radioactive isotopes present in small amounts. This line of thought induced us to investigate the properties of samarium and we found this element to be markedly radioactive.

The activity of samarium oxide is a third of that of a thick layer of potassium chloride of equal surface. It is not due to the presence of any known radioactive element. This follows partly from the fact that efforts to separate the activity by precipitation with barium, lead, zirconium and so on failed and partly from the properties of the radiation emitted. The intensity of the latter is decreased to half its value by a thickness of aluminium of $1 \cdot 3$ μ. Measurements made by the method of Geiger and Klemperer indicate that the radiation is of the α-ray type.

This kind of radiation has not previously been

known. The close vicinity of samarium to the presumably very rare element 61 suggests that the activity may possibly be due to the presence of the latter. However, preparations of samarium so far investigated, mostly kindly given to us by the late Baron Auer von Welsbach and by Prof. Rolla of Florence, all show the same activity.

New Isotopes of Mercury

IN the course of some tests with very sensitive Schumann plates supplied by Messrs. Adam Hilger, I have obtained mass-spectra of mercury of an intensity greater than any previously photographed. On the best of these there are unmistakable traces of two new lines 197 and 203. The first is certainly due to a new isotope. The chance that the second is a hydride of the strong line 202 is considered small, for the conditions were unfavourable to the formation of hydrides, while under very favourable conditions in previous experiments no trace of the line had been seen. Their abundance was estimated by comparison with the faint isotope 196 previously determined to be present to the extent of 0·10 per cent. Assuming this figure, photometry indicated that 197 and 203 were present roughly to the extent of 0·01 and 0·006 per cent respectively. Their effect on the mean atomic weight will therefore be quite negligible.

Monoacetone Hexuronic Acid

TWENTY grams of hexuronic acid, prepared by Svirbely and Szent-Györgyi, were shaken in 500 c.c. of acetone in the presence of 50 grams of anhydrous copper sulphate for twenty-four hours. After filtration, the fluid was evaporated *in vacuo* to one third of its volume. On addition of a double volume of petroleum ether the monoacetone derivative of hexuronic acid crystallises out in well-formed large, colourless prisms or long needles. These were dissolved in acetone and recrystallised by the addition of petroleum ether. Seventy per cent of the theoretical yield was obtained.

The same substance was obtained when five per cent sulphuric acid was added to the acetone solution of hexuronic acid. After standing overnight, the sulphuric acid was removed by anhydrous sodium carbonate. Further treatment as above gave a yield of fifty per cent.

The acetone derivative is freely soluble in water, methyl and ethyl alcohol and pyridine, less freely in acetone or ether, insoluble in petrol ether or benzene. The melting-point is 220°–222° C. with decomposition. It causes a big depression of melting-point in hexuronic acid (melting-point of hexuronic acid 192° C.). The aqueous solution of the substance reduces silver nitrate, Fehling's solution, and iodine in the cold. The equivalent weight, estimated by iodine titration, is 107; the molecular weight is thus 214 (calc. 216). Analysis gives:

	Experiment.	Theoretical.
Carbon	49·82 per cent	49·9 per cent
Hydrogen	5·90 ,,	5·6 ,,

The specific rotation of hexuronic acid, and the monoacetone derivative, are (at 20° C.):

	Hexuronic acid.	Monoacetone Hex. Ac.
In water	+ 24 (C, 1·0)	+ 20 (C, 1·04)
In abs. ethyl alcohol	+ 58 (C, 1·03)	+ 15 (C, 1·02)
In abs. methyl alcohol	+ 50 (C, 1·0)	+ 28 (C, 1·03)

The acetone derivative is readily decomposed by water into acetone and hexuronic acid, which latter substance can easily be recovered quantitatively. Accordingly, dissolved in water, the molecular rotations of hexuronic acid and of its acetone derivative were found to be the same (actually 4224 and 4321 respectively).

This investigation has been aided by a grant from the Josiah Macy, Jr., Foundation.

Thermo-Optical Dissociation of Sulphur Dioxide

THE absorption spectrum of sulphur dioxide vapour in the far ultra-violet, which has been investigated by Henri[1] and Wieland between 2,500 and 2,000 A., has now been extended up to 1,700 A. by means of a 2 metre vacuum spectrograph. The analysis of the bandheads will be published in a later paper. Here I am discussing a dissociation process connected with this band spectrum.

The rotational structure of the SO_2 bands disappears gradually at about 1,900 A. This limit of pre-dissociation corresponds to a dissociation of SO_2 into SO + O + kinetic energy, as has been shown by Franck, Sponer and Teller[2]. Now there is no sign of dissociation at room temperature, obviously because the dissociated products recombine instantaneously. But at a temperature of 450° C. and a pressure of 1·5 mm. the absorption spectrum changes completely. The SO_2 bands are replaced by two quite different band systems, a faint one between 2,850 and 2,570 A., which is identical with the well-known S_2 bands, and a strong one between 1,800 and 1,650 A., which does not seem to have been known before, but which very probably also belongs to S_2 (the combinations demand a vibrational frequency of 725 cm.$^{-1}$ in the ground state). At the same temperature and a somewhat higher pressure of 4·5 mm. both the SO_2 bands and the S_2 bands are visible. After recooling the absorption tube at 20° C. the spectrum shows the unchanged SO_2 bands alone as before heating.

These results suggest a dissociation of SO_2 into $\frac{1}{2}S_2 + O_2$. (The absorption spectrum of O_2 at a pressure of 1 or 2 mm. is too faint to be observed in a 5 cm. tube.) Now a purely thermal dissociation of SO_2 requires an energy of 83 kcal. (or 3·6 electron-volts) (SO_2 + 251·5 kcal. = $\frac{1}{2}S_2 + O_2$ + 168·7 kcal.) and consequently cannot be caused by raising the temperature to 450° C. only (energy of thermal agitation 0·03 electron-volts). On the other hand, an optical decomposition requires 6·5 electron-volts, if the dissociation process takes the following course:

$$SO_2 + 6{\cdot}5 \text{ electron-volts (predissoc.)} = SO + O + 0{\cdot}9 \text{ electron-volts (E kinet.)}.$$
$$SO + 5{\cdot}1 \text{ electron-volts (predissoc.)}^3 = S + O.$$

But although the light of the hydrogen lamp is photochemically active below 1,900 A. (6·5 electron-volts) it does not have any appreciable decomposing effect on SO_2 at room temperature. Thus a combined thermo-optical effect only can be responsible for the

observed dissociation. Such an effect can perhaps be understood from a theory on the predissociation of polyatomic molecules, as has been pointed out by Franck, Sponer and Teller[2]. According to these authors the spectral range of predissociation (which is identical with the range of the photochemically active light) even if quite small at low temperatures, can extend very much with increasing temperature. Thus at a high temperature the light of the hydrogen lamp, being photochemically active over a much wider range than at room temperature, could produce an appreciable decomposition of SO_2.

A more detailed paper on this subject will appear shortly.

'Protective' Adaptations of Animals

ON the subject of "ant-mimicry" Mr. Uvarov states[1] on McAtee's authority, "that more than three hundred species of American birds (out of the total number of about eight hundred species including non-insectivorous ones) feed on ants and some of them consume thousands of individuals." He does not seem to have noticed the consequences of McAtee's method in tabulating "the total number of identifications . . . from these stomachs, counting those of whatever degree, once for each time identified, irrespective of the number of individual specimens concerned"[2] (p. 7). Therefore a bird's stomach containing a single ant or a very small number, liable to be swallowed accidentally with other food, would lead to the obviously absurd conclusion that the bird feeds on ants. A woodpecker's stomach containing 2,000 ants (p. 93) supplies evidence which, on this system, is of no greater value than a stomach containing a single ant. It is much to be regretted that McAtee, with all this vast material before him, did not publish all the available data which would have enabled us to know more of the real and habitual enemies of ants as well as of other insects. Mr. H. B. Cott has done this work admirably in his paper[3] on the tree-frogs of the Lower Zambezi. Here we are given incontrovertible evidence that certain species regularly feed upon these powerful and aggressive insects. But who doubts that they have many enemies? Yet it will, I think, be clear to anyone who reads Mr. C. Elton's interesting paper[4] on "Territory among Wood Ants", that insects mistaken for ants in Dr. T. G. Longstaff's bird sanctuary at Picket Hill would, on the whole, be benefited by the resemblance and that the chance of being eaten as an ant by the green woodpecker would be a risk well worth taking.

Those who maintain with Mr. Uvarov that because ants have many enemies there can be no advantage in the mimicry of ants might with even greater force argue[5] "that the danger would far outweigh the advantage of the well-known longitudinal stripes and green colour borne by grass-feeding larvæ". Think of the larger mammalia whose existence is bound up with the grasses. How dangerous to resemble grass when such quantities are eaten at a single meal by these huge animals!

So far from the following line of argument, advanced in 1898,[6] bearing the "aspect of a beautiful fairy-tale" I believe that it is reasonable and will not be lightly dismissed. "When one insect resembles an ant by the superficial alteration of its whole body-form, another by the modifications of a shield-like structure which conceals its unaltered body, another by having the shape of an ant painted, as it were, in black pigment upon its body while all other parts are concealed [by colour]; another by a further modification of its body, so that it represents not an ant only, but the object which the ant is almost always carrying—when the effect of all these results is heightened by appropriate habits and movements, we are compelled to believe that there is something advantageous in the resemblance to an ant, and that natural selection has been at work".

I certainly did not allege in a former letter[7] that Mr. Uvarov had willingly misrepresented the opinions of others. On the contrary, I expressed the conviction that he would *not* willingly do so. Nevertheless his statement, "taken almost verbatim from the original paper", that "A common objection to this [McAtee's] method is that anything found in a bird's stomach would be in an unrecognisable state" is inaccurate and misleading. This supposed "common objection" is not the only rash and incorrect statement or inference in McAtee's paper. Others were criticised at the International Congress of Entomology in Paris last July in a paper which will appear in the forthcoming volume of *Proceedings*. Fellows of the Entomological Society of London and their friends will have the opportunity of hearing further criticisms at the meeting of December 7.

I trust that those who are interested in these important and far-reaching questions will carefully study Dr. F. Morton Jones's paper on "Insect Coloration and the Relative Acceptability of Insects to Birds", which will appear in the forthcoming part of the *Transactions of the Entomological Society of London*.

I cannot conclude without commenting on one other statement in Mr. Uvarov's letter. Referring to the "great problem of natural selection", he writes—"it is time that attempts were made to elucidate it by an unbiassed accumulation of facts". He does not appear to know that one of the greatest problems of natural selection, forming the subject of this correspondence, has been elucidated, and successfully elucidated, by the careful and unbiassed observations of many naturalists, during the past thirty-six years. I need only mention G. A. K. Marshall,[8] C. F. M. Swynnerton,[9] and G. D. Hale Carpenter[10]—naturalists whose work has been undervalued or altogether neglected by McAtee, and now by implication in the above-quoted sentence by Mr. Uvarov.

Delayed Split and Pairing of Chromosomes at Meiosis

SOME recent claims in connexion with the cytological explanation of meiosis raise very important questions when taken in conjunction with morphological development. This matter is brought to a climax by the recent report in NATURE of a paper read by Prof. C. L. Huskins[1] to the Royal Society of Canada.

Until recently, pairing in meiosis was generally considered to be due to the occurrence of two sets of like chromosomes, one set from each parent. Cytological study of triploids, tetraploids, etc., and of the detailed structure of chromosomes during pairing caused doubt to be thrown on this interpretation. Evidence and conclusions from it were discussed by Darlington[2] in NATURE. He points out that the threads first discernible in the prophase of mitosis are paired (pairs of chromonemata), whereas in meiosis they are single (chromosomes) but later come together in pairs and, still later, split. Then he states the chiasmatype theory of meiosis, that the pairing of chromosomes (not chromonemata, as in mitosis) is due to a delayed splitting and that the immediate cause of pairing is the chiasmata. The following are quotations from the article referred to:

(1) "Evidently, therefore, the single threads at the earlier stage were chromosomes still undivided although in the earliest visible stage in mitosis they have already divided" (p. 710).

(2) "These observations point to the chiasmata being the immediate cause of pairing between chromosomes" (p. 710).

(3) "The prophase of meiosis therefore starts too soon, relative to the splitting of the chromosomes" (p. 711).

(4) "The decisive difference would therefore appear to be in the singleness of the early prophase threads in meiosis" (p. 711).

Hedayetullah[3] in a very careful and detailed study of the somatic chromosomes of *Narcissus* found that the chromosome consists of two chromonemata each of which splits at metaphase into the two chromonemata of the newly constituted chromosome. The chromosomes at anaphase and metaphase of mitosis thus show as double structures (pairs of chromonemata).

In a paper read on August 22 before Section M of the Australian and New Zealand Association for the Advancement of Science,[4] I pointed out that the double structure of the anaphase and telophase mitotic chromosomes is not consistent with the single structure of the early prophase meiotic chromosomes; and that the resolution of this inconsistency requires a study of the last premeiotic mitosis (a study about to be taken up in *Acacia Baileyana* where that mitosis can be identified with certainty). In the issue of NATURE received in Australia this week, there is the report of an answer to this question by Huskins[1], who finds that the metaphase split of the chromonemata does not occur in the last premeiotic mitosis.

While Huskins' work appears to resolve the difficulty outlined above, it raises further very far-reaching and important questions. Now, in most ovules and some anthers the last premeiotic division results in the formation of primary parietal and primary sporogenous cells. If in this division the chromosomes emerge not split, then the conditions for meiosis must occur in both primary parietal and primary sporogenous cells of many plants. Darlington[2] (p. 711) says: "If we consider that there is a universal attraction of threads in pairs at the prophase of any nuclear division, as we see it at mitosis, it follows that this condition is fulfilled by the pairing of chromosome threads when they are still single", also quotations (3) and (4) above. Why, then, does not meiosis occur also in the primary parietal cells of those plants the primary sporogenous cells of which function as mother cells? Such a question (*mutatis mutandis*) becomes still more acute when the archesporial cell functions as a mother cell.

I am undertaking work on the cytology of *Acacia Baileyana* to seek some contribution to the solution of these problems.

It is worth noting that the larger microsporangia which are more easily handled for plant cytological study would not have a morphology that calls up the questions just brought forward. Moreover, it is notorious how little cytological work is done on megasporogenesis where such questions would inevitably arise. Perhaps one might close with a plea for a closer association of cytology with the study of morphological development.

Motions of Bodies of Oil on the Surface of Alcohol-Water Solutions

THE reaction was first observed when preparing a solution of spirit and water in which to suspend a body of oil as a sphere. The density of the solution was too great, and the oil rose to the surface as a thick lens-shaped drop. In this state, it was observed that the drop always moved away from an observer, and, on investigation, this was found to be due to the heat of the observer's body.

The effect was used to illustrate surface tension, but, after numerous repetitions, it was noted that the drop always tended to return to a unique position on the surface of the solution very soon after the disturbing cause was removed, for example, by the observer vacating the room for a few minutes.

To test this fact, the flask was shaken and replaced. This did not modify the tendency of the drop to return to its place on the liquid surface; this place was then named, for convenience, the rest-position; it was found to be invariable, in any given position of the flask in the room, so long as the heat field of the room remained tolerably constant.

Further tests of this phenomenon were made by placing the flask on a turn-table and rotating it; in all cases it was found that the drop returned to its rest-position as soon as the solution ceased to rotate.

Reactions were found to take place in flasks and beakers of glass, china, and metal, but they appeared to be modified by the substance of the vessel. All reactions are modified by plane or curved surfaces of glass, metal, paper, etc., placed outside a vessel like reflectors; they modify the motion from a warm body, and they modify the path of return to the rest-position, according to the angle at which such reflectors are set.

There is reason to believe that a magnetic field modifies reactions; it is still in doubt whether a moving magnetic field produces motion in an oil drop.

Light radiation has been found to cause displacement of a drop under conditions which prevented a heated body from producing any reaction. The question remains open whether some portion of light energy had been converted into heat.

Energy given out by an electrified body causes motion of a drop.

It seems probable that those who are interested, and who have facilities for strictly eliminating given forces, will find that all forms of radiation are effective in causing displacement of a drop.

Experiments have been made and repeated numerous times with flasks in lines and in groups. The motions of drops in flasks in groups are suggestive of speculations which it would be premature to present seriously.

All the work has been done with alcohol-water solutions. The reason was that other solutions were tried, but observations were embarrassed by secondary phenomena which could be excluded only by using a fairly constant liquid solution.

It may be mentioned that some experiments were made with an oil drop suspended between a water surface and a petrol surface; the results were quite indefinite, but they seemed to indicate a possibly interesting line of investigation.

The proportions of alcohol to water respectively 1:4 give satisfactory results with the oils named; exact density is not important, but homogeneity of solution is essential. A liquid surface about 10 cm. in diameter with an oil drop about 15 mm. diameter is convenient for observation.

The working hypothesis has been that a liquid surface is, in effect, a neutral gravitational plane where abnormal displacements may be caused by infinitesimal forces.

Glemham, C. T. JACOB.
Harpenden Rd.,
St. Albans.
Oct. 28.

I THINK probably no unusual forces are involved in the motions of oil drops floating on water-alcohol solutions described by Mr. Jacob. A liquid surface, unless of enormous extent, is not a plane; the influence of the curvature at the walls extends several centimetres to the interior of the surface. It is probable that the curvature of a liquid surface in a vessel ten centimetres diameter, or even larger, would be sufficient to cause a floating drop to seek the central position, that is the lowest, by simple gravitational forces; it would move downhill. The curvature in the central part of such a surface would be so small, that very minute forces would suffice to displace the drop from a strictly central position. In the presence of minute, but permanent convection currents caused by differences of temperature in the different parts of the vessel, the position of rest might be some distance from the centre, the natural tendency of the drop to move to the lowest point being balanced by a steady convection current. It is possible that the effect of the electric field in moving the drops is due to a charge on the surface of the drop; but the equilibrium is so easily disturbed that it seems possible that all the phenomena may be due to convection currents, balanced against a minute gravitational restoring force.

Abnormal Winds in Cordoba

FOR some months past—since about June to the best of my recollection—we have had an abnormal amount of wind from the east and south-east. In fact it could be said that such were and are still the *prevailing* winds.

Ordinarily the winds in Cordoba are from two opposite directions—north to north-east, warm, dry winds, accompanied by clear skies which usually occur the greater part of the time; and cold, strong winds from the south to south-west which follow the passing of a 'low' to the north, for a few hours or a day, seldom longer, often cloudy and with rain. The nights on the pampa are with few exceptions calm. The few exceptions are when a 'low' is passing and not always then. At altitudes above 1,500 metres there are usually high winds at night.

West winds are practically unknown and winds from the eastern quadrant almost as rare, in normal times. For those reasons the large amount of east and south-east winds during the past winter is outstanding and undoubtedly significant.

What is the cause of these deflections? It appears to be suggestive that they are of the kind that might be expected if influenced by the volcanic eruptions in the Andes. The centre of these eruptions is in a latitude slightly south of Cordoba, so that the south-east winds would be blowing counter-clockwise about that region of eruption as about a cyclonic area—a high temperature 'low'.

These south-east winds observed here are *surface* winds, of course, and I have no means of knowing whether the winds in other regions conform to such a possibility or not, or whether the winds at higher altitudes have been affected also.

These east to south-east winds have been accompanied by unusual cloudiness and humidity, and just recently by heavy precipitation in the region to the east, traversed by these winds from the Atlantic, inundating thousands of hectares and destroying the crops. Whether or not the volcanic eruptions have anything to do with the abnormal direction of these winds will require a study of extensive data. If such is not the cause there is some other. From time to time news comes of outbursts from the volcanoes in the Descabezada region. I do not know if they are in continuous eruption, but from the presence of volcanic ash in the air almost continuously during the winter, it seems probable that such has been the case.

The object of this note is to direct attention to a matter which appears to be worth investigating.

The Hon. Mrs. Huia Onslow

IT has been decided to prepare a memoir of the late Hon. Mrs. Huia Onslow, better known to the scientific world as Muriel Wheldale Onslow, whose obituary notice appeared in NATURE of June 11, 1932. I shall be very grateful if those who have letters in their possession written to them by Mrs. Onslow would kindly lend them to me for this purpose. They should be addressed to me and will be carefully preserved and returned to their owners.

Stone Implements of Choukoutien.—More abundant archæological material and further field work have made desirable a new and supplementary exposition of the facts relating to the stone industry of the Peking man deposits by P. Teilhard de Chardin and Dr. W. C. Pei (*Bull. Geol. Soc. China*, 11, No. 4). The sediments of the Choukoutien Locality 1 (*Sinanthropus* cave) are a massive hard breccia in which at least three cultural zones can be distinguished. The entire deposit of Zone *A* is of red, yellow and black banded sandy clay in which *Aa*, by a dense accumulation of quartz chips and burnt bones, is strikingly similar to the classical culture layers of the western European caves. Zone *B*, remarkably interesting stratigraphically, has yielded but a small series of flaked boulders (choppers). Zone *C*, with the implements of which this communication deals chiefly, is especially significant as the artefacts were discovered in association with *Sinanthropus* remains. Zone *C* has exactly the same lithological character as Zone *A*. The fauna collected in association with ashes and stone artefacts is abundant and characteristic (*Equus sanmeniensis*, *Rhinoceros 'sinensis'*, *R.* cf. *tichorhinus* (?), *Elephas nomadicus*, etc.) Outside the three zones, artefacts are found from place to place and more may be forthcoming. In Zone *C* several thousands of minor fragments of stone have been found and more than a hundred chipped or intact foreign boulders. The stone is green sandstone, commonly, but also vein quartz and, exceptionally, quartzite or quartz-porphyric rock. Provisionally the specimens are classified as flaked boulders, truncated boulders, choppers, quartz cores, scrapers, pointed implements, and chipped or flaked limestone pieces, possibly anvils or hammer stones. The provisional opinion is expressed that the industry of Zone *C* moderately, but distinctly, exceeds what would be expected to be the most primitive recognisable human industry. The makers already had some definite methods of choosing, breaking and adapting stone to several uses; but in so doing they obeyed, rather than mastered, their material.

Prehistoric Cults in Portugal.—The connexion between Christian shrines and prehistoric sites which has been shown to be highly probable in the instance of Saint James of Compostela in Spain, is demonstrated to be equally probable in Portugal by the Rev. E. O. James in a communication which appears in *Folk-Lore*, vol. 43, No. 3. At Mattosinhos, a few miles from Oporto, is the church of Bom Jesus de Boucas, said to be the oldest shrine in the country, which is visited annually by 30,000 pilgrims. The present church was built in the sixteenth century to house a miracle-working cross, alleged to have been carved by Nicodemus, which floated to Portugal from Joppa under divine guidance. It landed at Leixões, a well-known harbour and refuge for vessels avoiding the treacherous bar of the Douro. Although there is no evidence of megalithic monuments in the neighbourhood of Leixões, a pile of rough stones, now surmounted by a tower, stands behind the chapel which marks the landing-place of the cross, and the whole tradition of Mattosinhos points to a legend of the Santiago type. The country to which the Douro gives access is a wide productive belt full of mines, especially of tin and gold, which were worked by the Romans, and presumably long before their day, while there is evidence of important ancient settlements in the province of Minho. The hermitage of São Romão was founded on the site of a ruined Romano-Celtic town. To this hill pilgrimages have been made annually on August 9. Braga, the seat of the primate of Portugal, is the Roman Bracara Augusta. Near it is the sanctuary of Bom Jesus do Monte, visited by thousands at Whitsuntide, and beyond it is another holy hill, the shrine to the Virgin of Sameiro. On the way up to the latter is a small dolmen, revealed in making a motor road.

Psychological Effects of Noise.—The effect of noise on the human mind and body is a problem of much practical importance. Does noise diminish efficiency and increase liability to accidents? Is there any evidence that it plays a part in the development of nervous and mental disorders? Two recent investigations, one in a laboratory and the other in a workshop, seem to indicate that noise is not a negligible factor in determining industrial efficiency ("Psychological Experiments on the Effects of Noise", by K. G. Pollock and F. C. Bartlett. "The Effects of Noise on the Performance of Weavers", by H. C. Weston and S. Adams. Industrial Health Research Board. Report No. 65. London: H.M. Stationery Office, 1932). Pollock and Bartlett, studying the psychological effect of noise on a simple motor skill and upon mental work in a laboratory, found a diminution of efficiency at first but this initial effect appeared to be only temporary. Weston and Adams carried out their investigation in a Lancashire weaving shed and used ear protectors on the workers to reduce noise. The effect was an increase of about one per cent in the average hourly output. The authors find evidence which suggests that even after years of work in a noisy environment the worker does not become completely adapted to noise. As is inevitable in any preliminary work, these two studies open up at least as many problems as they claim to solve, but taken together they indicate that noise may under certain conditions exercise a disturbing effect upon human efficiency, though to a less degree than is commonly supposed.

Phases of Locusts in South Africa.—Under the foregoing title Prof. J. C. Faure of the University of Pretoria contributes an important paper, of general scientific interest, occupying part 3 of vol. 23 of the *Bulletin of Entomological Research* (September, 1932: pp. 293–405, plates 14–38 and one map). Prof. Faure discusses the main theory of locust phases, due to Uvarov, and proceeds to detail the results of an extensive series of experiments designed to test the theory in so far as South African locusts are concerned. Most of his work was undertaken with the brown locust, *Locustana pardalina*, a species of prime importance in South Africa. His results show that 97 per cent of hoppers in the gregarious phase was obtained in the F_1 generation from adults in the solitary phase taken in the field, by rearing the progeny in a dense crowd. Other experiments showed that locusts in the solitary phase, if collected early enough in their development as hoppers and crowded in cages, acquire the coloration of the gregarious phase before reaching maturity. Owing to the fact that no swarms exhibiting the extreme characteristics of the

gregarious phase occurred in South Africa while the work was in progress, it was not possible to investigate similarly the transformation in the opposite direction, that is, from the gregarious phase to the solitary one. Recourse was consequently made to material in the gregarious phase obtained in cage experiments and to hoppers showing gregarious characters obtained from eggs laid by caught individuals in the transient or intermediate phase. By isolating individuals singly in cages, Prof. Faure was able to show that transformation from the gregarious phase to the solitary phase actually took place under these conditions. Detailed examination of the coloration and of biometric data indicated that actual phases, comparable with those occurring in the field, were obtained. The same conclusions were arrived at with regard to experiments conducted with the subspecies *migratoroides* of *Locusta migratoria*. The effects of environment on colour forms, the influence of heredity on phase production and other experiments are also recorded in this paper. The most important results achieved are shown in the experimental production of one locust phase from another, thus confirming in a significant manner the general truth of the phase theory.

Transmission of Light through Air and Water.—Quantitative measurement of solar radiation, never easy, is not made easier when the passage of light through sea or lake water has to be studied on board ship. Dr. W. R. G. Atkins, in "Solar Radiation and its Transmission through Air and Water" (*J. Conseil International pour l'Exploration de la Mer*, 7, pp. 171–211, 1932) has summarised his own work with Dr. H. H. Poole, as well as that of other workers on both sides of the Atlantic. He proceeds from the examination of light as it reaches the earth by means of colour filters and photoelectric cells to the penetration of light through water. For this purpose recent workers have favoured the pyrlimnometer (effectively a thermopile) and the photoelectric cell. Atkins has found the vacuum cell more reliable than the gas-filled. The photoelectric current may be measured either potentiometrically or by means of the neon lamp. The apparatus assembled for the United States research ship, *Atlantis*, is illustrated.

Thermophilic Amœbæ.—Dr. L. G. M. Baas Becking, Botanical Institute of Leyden, Holland, reports the presence of cysts of an unclassified amœba in waters collected from the hot geysers of Yellowstone Park, U.S.A. These cysts began to germinate on the hot stage at 50°–52° C., and withstood a temperature of a little above 60° C., for an hour. The thermophilic characters of this organism, therefore, approximate to those of the amœbæ recorded by Dr. E. Hindle from the thermal springs at Dax, near Bordeaux (see NATURE, 130, 780, Nov. 19, 1932). It is probable that the examination of material from similar sources would reveal the existence of many other examples of micro-organisms living at high temperatures, in addition to the well-known thermophilic bacteria.

Frost Protection for Plants.—The practical gardener has to wage continual war with frost in the late spring and early autumn, even in Great Britain, but the problem is more acute in the United States. Many types of protector have found their way on to the market, and the relative merits of some of these, together with a physiological study of frost protectors in general, form the subject of Technical Bulletin No. 124 of the Agriculture Experiment Station of the Michigan State College ("The Various Effects of Frost Protectors on Tomato Plants" by R. P. Hibbard, pp. 1–36, 1932). The protectors were in the form of more or less conical caps made from transparent paper or cellulose preparations. In one year of the six during which they were under test they were of definite benefit in preventing frost damage to young tomato plants, in two years of doubtful benefit and in three years none at all. They caused a diminution in intensity of light which was often detrimental, though protected plants were usually larger than unprotected plants. The author believes that the raising of twice as many seedlings as are really wanted is a surer and more economical insurance against damage by frost, since half can be planted early and the other half used to replace them if necessary.

Origin of Leucitites and Related Rocks.—A detailed account of the petrology of the volcanic fields near Ruwenzori has been prepared by Prof. A. Holmes, with chemical analyses by Dr. H. F. Harwood (*Quart. Jour. Geol. Soc.*, pp. 370–442; 1932). The associated rocks include olivine-leucitite, leucitite, potash-ankaratrite, melilite-basalt, and biotite-pyroxenite. It is pointed out that the limestone assimilation hypothesis of Daly and Shand provides no way of ensuring an excess of potash over soda such as characterises the province under discussion. Moreover, no limestones are present either in the rocks exposed at the surface or among the ejected blocks, which provide samples of the underlying crust to a considerable depth. The absence of granitic and basaltic rocks, of related types, and of felspars, suggests that any hypothesis invoking granitic or basaltic origin is untenable for this particular province. The rocks have marked geochemical peculiarities which relate them to kimberlite, the rock of the diamond pipes of South and Central Africa, and this suggests a magmatic ancestry in which peridotite magma plays the parental part. It is thought probable that the magmas of kimberlite and olivine-leucitite may be generated by the abstraction of the constituents of eclogite and dunite from a primary peridotite magma under conditions of high pressure, and that the magmas of melilite-basalt and alnoite may be generated under conditions of somewhat lower pressure by the early crystallisation of enstatite as well as olivine. Evidence of the separated crystalline phases is traced in the eclogite and dunite nodules of the diamond pipes and in the enstatite phenocrysts of the melilite-basalt tuffs of Uganda.

Radium in Hungarian Rocks.—The radium contents of some Hungarian igneous rocks have been determined by S. S. de Finály, using the method of Mache and Bamberger. The results for sixteen rocks, together with new chemical analyses of each, have now been published (*Amer. J. Sci.*, Oct., p. 306). Ten granites gave amounts ranging from $1 \cdot 43$ to $3 \cdot 69 \times 10^{-12}$ gm. of radium per gram of rock, the average being $2 \cdot 50 \times 10^{-12}$. The latter is close to the European average so far determined, but is higher than that for the otherwise similar rocks of eastern North America. In four andesites the radium ranges from $1 \cdot 64$ to $2 \cdot 38 \times 10^{-12}$, and averages $1 \cdot 96 \times 10^{-12}$. In two 'basalts', which seem to be wrongly named in view of the chemical analyses, the radium contents are respectively $1 \cdot 48$ and $1 \cdot 93 \times 10^{-12}$.

A High-Voltage Generator.—The *Physical Review* for October 15 contains an interesting suggestion for a high-voltage generator. It is known that large frictional charges are produced by blowing dust-laden air against a conductor. Experiments show that a charge of 6×10^{-6} coulombs can be produced by blowing 1 gm. of diatomaceous earth, and it is suggested that a machine could be constructed to generate 1 milliampere at potentials of the order of one million volts. An experimental apparatus was constructed in which 1·5 gm. per second of diatomaceous earth was blown through insulating tubes and then through metal tubes arranged diametrically in a spherical corona shield. A voltage of 260 kilovolts was obtained and a current of 8×10^{-5} amperes could be drawn from the sphere at this voltage.

Collisions of Neutrons with Electrons and Atomic Nuclei.—Dr. H. S. W. Massey has discussed (*Proc. Roy. Soc.*, Nov.) the collisions of neutrons with electrons and atomic nuclei. The model of the neutron used is a hydrogen atom in a nearly zero quantum state—this model is not admitted by ordinary quantum mechanics, but a non-relativistic theory is certainly inapplicable to these conditions. The collision relations are worked out by the method of Born, Faxén and Holtsmark. The introduction of the value of the collision cross section with lead nuclei (presumably obtained from absorption experiments) allows an estimation of an upper limit for the radius of the neutron of $2·0 \times 10^{-18}$ cm. It is then found that the collision areas with light nuclei vary with the square of the nuclear charge—a much larger variation than is consistent with experiment. The author concludes that the collisions are determined by an internal nuclear field, the penetration being very close. In the case of protons the experiments also appear to require the interaction to be controlled by a powerful intra-proton field. The collisions of the model neutron with electrons are shown to be negligibly probable.

The Hydrogen Isotope, H^2.—In the *Physical Review* for October 1, K. T. Bainbridge describes measurements of the atomic mass of the hydrogen isotope H^2. The measurements are important as a clue to the structure of the H^2 nucleus, since the packing fraction and binding energy of the nucleus may be calculated from them. Ordinary hydrogen and hydrogen fractionated by Brickwedde were successively used in a discharge tube mass-spectrograph. With the enriched hydrogen an ion $H^1_1H^{2+}$ was observed and its position was compared on a microphotometer record with that of He^+. The mass found was 2·01351 ± 0·00018 ($O^{16} = 16$), and if the nucleus consists of two protons and an electron, the energy of binding is 2×10^6 volts. If the nucleus consists of a proton and a neutron of mass 1·0067, the binding energy is $9·7 \times 10^6$ volts. Dr. Bainbridge brings forward considerations to show that H^2 is not a very likely unit in the building up of heavier nuclei. In the *Physical Review* for October 15, Hardy, Barker and Dennison examine the infra-red absorption spectrum of hydrogen chloride. In some of the experiments, the gas was an enriched specimen prepared from electrolytic cell residues. The spectra showed band-lines corresponding to H^2Cl^{35} and H^2Cl^{37}; and calculations show that H^2Cl was present to the extent of about 1/35,000 in ordinary hydrogen chloride and about ten times as much in enriched specimens. On the assumption that the molecular fields were identical for H^1Cl and H^2Cl, the atomic mass of H^2 was found to be 2·01367 ±0·0001, in satisfactory agreement with Bainbridge's value.

Astronomical Topics

Standard Times throughout the World.—A useful brochure, with this title, published by the U.S. Bureau of Standards, contains maps and tables which give the differences between the times used at various stations and those of Greenwich and Washington. The maps bring out the fact that the boundaries of the successive hourly time zones are far from conforming with the theoretical meridians; in fact they are made to conform with the boundaries of States or countries. One might expect that the 180° meridian where the day changes, which is nearly all water, would be straight; but even this shows notable deflections. These irregularities emphasise the utility of such a publication as the present one; without it one might frequently make errors of an hour.

Spectrum of Epsilon Aurigæ.—An exhaustive study of the spectrum of this remarkable eclipsing variable star by E. B. Frost, O. Struve and C. T. Elvey has been published (Pub. Yerkes Observatory, vol. 7, pt. 2). It is chiefly based on spectrograms obtained at Yerkes in the years 1899–1901 and 1917–1931, but results obtained elsewhere have also been utilised. The curve of radial velocities from all sources shows a prolonged minimum about 1910 and another about 1930; the only maximum during the period discussed was about 1925; the extreme velocities are about −13 and +20 km./sec. The light-curve shows that an eclipse began in April 1928; the light declined steadily for six months, then remained constant for a year at 4·2 mag., then returned in six months to the normal value 3·4 mag. Asymmetry in the spectral lines begins about 200 days before the eclipse begins, and continues after it ends; the explanation given is that the eclipsing star has a very extensive atmosphere, the depth of which is determined from the measured velocities to be more than an astronomical unit; the light from the primary suffers absorption in this atmosphere. Other peculiarities in the spectral lines suggest that the secondary star has rapid rotation, producing an atmosphere flattened at the poles and extended at the equator. Its atmosphere is also concluded to be free from magnesium, as this is the only strong line in the spectrum of the primary that is not strengthened during eclipse.

The article also refers to Zeta Aurigæ, which has many points in common with Epsilon; but in its case the spectrum of the eclipsing star (of type *K*5) remains visible throughout the period.

Correction to "Astronomical Notes for December".—The times of occultations of stars by the moon given in NATURE for Nov. 26, p. 817, were those for Edinburgh; the times for London are: ι Aquarii, Dec. 3, 6^h27^m P.M.; μ Arietis, Dec. 9, 11^h8^m P.M.; ρ Leonis, Dec. 19, 0^h24^m A.M.; reappearance 1^h29^m A.M., angle 316°.

Prehistoric Sites near Flagstaff, Arizona*

SOME interesting inferences as to the geographical and economic factors involved in the development and distribution of prehistoric Pueblo culture in parts of northern Arizona are drawn by Dr. Harold S. Colton in a report on a survey of prehistoric sites in the neighbourhood of Flagstaff, which was carried out on behalf of the Museum of Northern Arizona in the course of ten summers between the years 1916 and 1930. It is the intention of the Museum ultimately to survey all sites in the northern area of the State, taking Flagstaff as a centre, but, for the present, attention is confined to those sites which lie to the east, between Flagstaff and the Hopi villages on the edge of the Painted Desert.

The area under investigation culminates in the San Francisco volcanic field, which is the second largest in the United States, and supports two hundred extinct cones, of which the highest form the massif known as San Francisco Peaks (12,700 ft.). From here the land slopes down into the valley of the Little Colorado River, rising again in terraces of vari-coloured cliffs, on the last of which stand the Hopi villages, to the Painted Desert.

The geological structure of the area is seen to have been an important factor in determining the distribution of prehistoric culture. Beneath the fields of volcanic ash and sand lie the Moencopi red sandstones and shales, the only rocks over a wide area which hold water. Wherever they have not been denuded, springs are found. Beneath them lie Kaibab limestone and Conconino limestone, both of which are waterless.

A further factor, which was discovered in 1930 only, is the recent activity of Sunset Crater in early Pueblo times. This was clearly a dominant event in the history and culture of the Pueblos. It took place somewhere between A.D. 600 and A.D. 850. A cover of black basaltic sand was then spread over the land for a radius of about twenty miles, in places near the crater to a depth of as much as two feet. It acted as a mulch, retaining the moisture and affecting the flow of the streams. It was eminently suited to the digging-stick type of cultivation affected by the Pueblo peoples. The population, which had hitherto congregated near the peaks, where a water supply was assured, is seen to have now spread densely over the area covered by the volcanic sand. They withdrew once more to the earlier sites near the peaks, or the shelter of the escarpment, when the prevailing winds in the course of time had removed the sand, except where anchored by vegetation, and had deposited it in the canyons, whence much of it has been carried away by the waters of the Little Colorado.

* "A Survey of Prehistoric Sites in the Region of Flagstaff, Arizona." By Harold S. Colton. Bulletin 104, Bureau of American Ethnology, 1932.

The operations of the survey with which Dr. Colton deals in the present publication recorded 728 sites situated in the drainage areas of two tributaries of the Little Colorado, Walnut Creek and Deadman's Wash. The intervening watershed is omitted for future consideration.

Four culture horizons were recognised, which, in accordance with the nomenclature now adopted in Puebloan archæology, are classed as Basketmaker III, Pueblo I, Pueblo II and Pueblo III. The tree-ring chronology worked out by Prof. Douglass on the basis of the growth of the trees used in Pueblo architecture, gives *circa* A.D. 900 for a few Pueblo II sites; for Pueblo III, *circa* A.D. 1050–1300; and for Pueblo IV, A.D. 1300–1600. Applying this scheme to sites in the Flagstaff area gives the following as approximate dating for certain sites: Wupatki, 1087–1197; Citadel, 1192; Turkey Hills, 1203–1278; Ruin J, 1192. Pueblo IV and V are not represented. It was in late Pueblo II and early Pueblo III that the improvement in the conditions of agriculture and irrigation afforded by the black volcanic sand fostered the spread of a dense population over a wider area. The sites of these periods are thickly distributed between the Peaks and the Little Colorado. Black basaltic sand first enters into the tempering of material used in pottery in middle Pueblo II.

It is also to be noted that in Pueblo II and Pueblo III the pottery complexes in the Walnut Creek drainage and Deadman's Wash differ markedly and point to a complete dissociation of the two areas in culture. For this entire separation of the two tribes no reason is at present apparent.

No less than eight characteristic types of the Pueblo dwelling have been recorded in the area. They range through all stages from pit-houses to the Puebloan masonry multicellular dwelling. Some of the most interesting and characteristic dwellings are the cliff-shelters of Walnut Creek, south-east of Flagstaff, where the Kaibab limestone, overlying a precipitous wall of Conconino sandstone, weathers characteristically in a series of steps forming ledges with overhanging roofs. Here on each tier, rooms have been built in single rows, though in one or two places outer rooms have been added. Several of the dwellings have seven and eleven rooms; one is estimated doubtfully at thirty rooms. The greater number of these sites belong to Pueblo II and early Pueblo III.

A beginning has been made in the further exploration of the whole area by excavation.

The Locust Problem

THE fourth report of the Committee on Locust Control of the Economic Advisory Council* contains a survey of investigations carried out in 1931, and a programme of work for 1932–33. Since the presentation of the previous report of the Committee, in 1930, invasions by the desert locust (*Schistocera gregaria* Forsk.) have continued in almost all the countries in Africa and western Asia that were previously affected. Further, a new and even more serious menace to agriculture in tropical Africa has presented itself in the appearance of great swarms of two other species of locusts, namely, the tropical migratory locust (*Locusta migratorioides* R. and F.) and the red locust (*Nomadacris septemfasciata* Serv.).

* Economic Advisory Council: Committee on Locust Control. Fourth Report: Survey of Locust Investigations in 1931 and Programme of Work for 1932–33. (Cmd. 4124.) Pp. 43. (London: H.M. Stationery Office, 1932.) 1s. net.

Information gathered from official sources shows that the damage caused by locusts during the present outbreak (the period 1927–31) can be estimated, in round numbers, as exceeding £6,000,000, while about £1,000,000 has been spent on control measures. The whole course of this outbreak clearly indicates how close is the dependence of the locust situation in any one territory on the general incidence of the pest over wide areas. This interdependence shows that it is almost futile to control locusts in a few isolated districts. There is an urgent need for concentrating on investigations into the original breeding grounds of each locust species. The discovery of such areas would open up the possibility of each species being dealt with under relatively localised conditions before it is able to spread and become diffused.

The events of the past two years all emphasise the urgency of discovering the specific factors that result in locust invasions in order that a far-reaching policy for the prevention, or at least the reduction of future outbreaks, may be devised. The Committee has drawn up a comprehensive programme of work that it recommends to be carried out in 1932–33 and undertaken through the Imperial Institute of Entomology. At the headquarters of the Institute it is advised that the collection, study and analysis of available information on the problems involved should be continued and extended. The work also includes the task of transferring all records, both old and new, of locust migrations and breeding to maps covering defined periods. Such maps should prove invaluable for tracing the courses of all known invasions and in serving as the basis for studies connected with them. Furthermore, as the Institute is acting as the recognised international clearing house for all information dealing with anti-locust investigation, in this way it is in a position to assist all countries directly affected by invasions. The collection of specimens from swarms appearing in different lands, and at diverse times, is also being undertaken and their availability at the Institute will provide essential material for biometrical and other studies of the phase problem.

The field campaign, drawn up by the Committee, covers the investigation of the life-cycles of the locust species already mentioned; studies of their swarming and transitional phases; the correlation of locust activities with meteorological data and the testing of control measures. These aspects of the work will continue under the direction of the Chief Locust Investigator, Mr H. B. Johnston.

The co-operation of the governments of all countries affected by locust invasions is a matter of prime importance. It is now recognised that investigations of the character planned require to be international if the basic problems concerned are to be fully solved. The Committee acknowledges the value of the co-operation already afforded by the French and Italian Governments, and by the administrations of British colonies and territories, but is anxious to develop mutual effort and the pooling of information on a much wider scale. Recommendations are consequently made that the Economic Advisory Council should invite the Secretary of State for Foreign Affairs to communicate copies of the present report with an expression of hope of co-operation, in the work now planned, of governments that were not represented at the Rome conference on locust control in 1931.

In the matter of finance, the recommendations of the Committee are on a very modest scale considering the importance of the schemes involved. The 1932–33 programme, as estimated, can be carried out at a cost of £3,800, of which £395 represents capital expenditure on tents, apparatus, etc., and £3,405 is recurrent expenditure mainly for salaries, wages and travelling charges. It is to be hoped that the campaign now taking shape will be allowed to develop so fully as possible, in view of the magnitude of the losses sustained through locust invasions in so many areas of the British Empire and indeed throughout the world.

A. D. IMMS.

The Rubber Industry of Malaya

A SERIES of memoranda with an introduction by Dr. H. A. Tempany which have recently been issued in Malaya deal with the position of the Rubber Research Institute of Malaya and indicate that four distinct proposals for the future are before the Board. The retrenchment memorandum put forward by the executive committee estimates 350,000 dollars as the sum on which the Institute's activities can be maintained. This involves a reduction in expenditure of 183,000 dollars and at a special meeting of the Board of the Institute held on June 28, the recommendations of the executive committee were adopted with minor modifications.

The proposal of the Hon. B. J. R. Barton that the whole of the work of the Institute should be amalgamated with the Department of Agriculture was prompted by the belief that, while the retrenchment proposals did not go far enough to bring relief to subscribers in any appreciable reduction in payment of cess, they would accentuate a feeling of discontent among the staff of the Institute and that the organisation would not represent the best possible in the interests of the Industry. Mr. Barton stressed the advantages of the Department of Agriculture and while the retrenchment proposals may involve curtailing the advisory work, the activities of the Institute can scarcely be maintained at more than a semblance of their present efficiency. The representatives of the Malaya Estate Owners Association urged that the situation should be investigated by an independent body, but this proposal was also negatived.

The proposals adopted by the Board, after accepting the view that 350,000 dollars represents the minimum upon which the activities of the Institute can be effectively maintained and the maximum which can be at present expected from the export cess levied on rubber, since the area of untapped rubber which escapes all contributions is expected to increase, provide for retrenchment by reduction in salaries, in the personnel and on allowances for cess, etc., on duty. In addition to a reduction of 5 per cent already imposed, a further reduction of 20 per cent on all salaries is now contemplated. With regard to personnel, the research services are graded in the order of importance, chemical, botanical, pathological, soils, field; and restriction of activity by reduction of personnel is advocated to fall with increasing incidence in the descending order shown above. On account of the increasing importance of latex, it is recommended that reduction in the chemical and pathological divisions where research on latex

is principally carried out should be a minimum.

The heads of divisions presented alternative proposals which also were not accepted. These proposals were backed by a strong plea that they were the outcome of careful thought by those who had exceptional opportunities of studying the working of the Institute and the needs of the industry. They recommend a complete reorganisation of the personnel and work of the Institute on two main lines: (i) work on the product—chemical; (ii) work on the tree—botanical, including agricultural and both research and advisory work. They envisage four senior scientific officers and one administrative officer working as an executive cabinet under a director, preferably someone quite free from outside affiliations and selected mainly for administrative ability and experience. Such a scheme, if staffed with officers capable of working in absolute harmony, should develop the team spirit essential to success. A selection and a list of temporary salaries were included with these proposals.

In view of the growing recognition of the importance of Imperial research on Empire products, it is disappointing to learn of this serious threat to rubber research and the uneasiness with which scientific workers and others regard the situation will not be diminished by the Board's dismissal of the alternative scheme and proposals put forward by the scientific and technical heads of divisions. The reductions in salary and personnel adopted by the Board appear likely to have an untoward effect on the recruitment for Imperial services abroad generally. In view of the comparatively early age of retirement in such services and the difficulty frequently experienced in securing an appointment on return to Great Britain, such drastic reductions in salaries will deter many promising scientific officers of high ability from coming forward for service abroad.

Ultra-short Wave Technique in Radio Communication

AT the International Congress of Electricity held in Paris in July last, some twenty-six papers were read before Section 9 dealing with various aspects of radio engineering, ranging from commercial telephonic communication to the study of the electrical properties of the upper atmosphere. Among these papers, two are of particular interest in connexion with the progress of ultra-short wave technique.

The first of these, by I. E. Mouromtseff and H. V. Noble, describes a new type of ultra-short wave oscillator. This consists of a special three electrode valve in which the cylindrical anode and spiral grid form part of a concentric transmission line, which itself replaces the tuned circuit normally associated with an oscillating triode. For cylindrical conductors the diameters of which are of constant ratio, the inductance and capacity of the line will satisfy the condition of uniformity of distribution, and when the necessary supply voltages are connected to the electrodes at suitable points oscillations will be set up on the line at a wave-length equal to twice the length of the line. These oscillations take the form of stationary waves giving rise to no external field or radiation, but a suitable open or closed circuit may be coupled to the line, in order to make use of the high frequency power. A large water-cooled transmitting valve constructed on this principle has been made to generate up to 16 kilowatts at wave-lengths of 3 and 5 metres, with an efficiency of from 20 to 40 per cent.

The use of this principle would appear to overcome some of the difficulties of making high-power valves for short wave-lengths, which arise from the necessity of reducing inter-electrode capacity in valve oscillators using one of the ordinary circuit arrangements. Since the reading of the paper in Paris, a more complete account of this work has been published in the *Proceedings of the Institute of Radio Engineers* for August 1932.

In the second paper, I. E. Mouromtseff and G. R. Kilgore give a description of some experiments on a magneto-static oscillator for the production of oscillations at wave-lengths of 50 cm. or less. The special valves employed are similar to the magnetron type, comprising a cylindrical anode, split longitudinally into two parts, and containing a straight axial filament. This valve is placed in a suitable coil supplying a constant magnetic field in the direction of the axis. The two halves of the anode are connected to two parallel wires forming a Lecher wire system which can be adjusted to resonate at the desired wave-length. Yagi and Okabe had previously remarked that, in the ordinary magnetron, when the conditions were such that the electrons passed very close to the anode without touching it, weak oscillations of a very high frequency were to be observed.

The present researches show that the intensity of these oscillations can be enormously increased if the direction of the magnetic field is altered by a small angle from the axis of the valve electrodes. Graphs accompanying the paper referred to above, show that the oscillations attain a maximum intensity for angles between 2° and 10°, depending upon the dimensions and operating conditions of the valve. Examples are quoted in the paper of valves capable of producing oscillations of appreciable intensity at wave-lengths of 22–55 cm. R. L. S.-R.

University and Educational Intelligence

BIRMINGHAM.—The Executive Board of the Birmingham Hospitals Centre, of which Sir Charles Grant Robertson is chairman, has decided to proceed immediately with the provision of the new hospital at Edgbaston on the site of 100 acres adjoining the University given by Messrs. Cadbury Brothers. The first instalment is to consist of 500 beds. This scheme (which has been suspended for many months in consequence of the national financial stringency) is of vital importance to the University, the Medical School of which is to be housed in buildings forming part of the hospitals centre. It has been disclosed that a contribution of £52,000, hitherto anonymous, was made by Sir William Morris (of Morris Motors Ltd.) on the understanding that the work should be begun by January 1, 1933. A donation of £100,000 was made by Mr. Harry Vincent, treasurer of the fund, and another contribution, by an anonymous donor, of £50,000 has been received. The total cost of buildings and equipment is estimated at above £718,000, of which more than £647,000 has already been contributed or promised.

CAMBRIDGE.—The General Board has recommended that vertebrate zoology be added to the list of sub-departments in the Department of Zoology, with the reader in vertebrate zoology as director of the sub-

department. It has also recommended that a readership in vertebrate zoology be established and that Mr. C. Forster Cooper, of Trinity Hall, be appointed to the readership as from October 1, 1932.

EDINBURGH.—A legacy of £1,300 by the late Prof. Baldwin Brown has been received to establish a "Baldwin Brown Travelling Scholarship in Fine Art" for the benefit of women students in the subject of fine art. It is to be used for the study of archæology, painting and sculpture and the decorative arts among the buildings and collections of England, France, Belgium and Holland.

WALES.—The Council of the Welsh National School of Medicine has appointed Dr. J. B. Duguid as professor of pathology and bacteriology, and Dr. G. I. Strachan as professor of gynæcology.

THE quarterly record of current educational publications issued by the Office of Education, Washington, is, in its recently improved form, an invaluable instrument for enabling teachers in the United States (where about a million persons are, it is said, engaged in educational work) to keep abreast of the literature of their vocation. It includes a classified and annotated list of significant publications selected by specialists in each of the following fields: nursery-kindergarten-primary, elementary, secondary, exceptional children, educational psychology, junior colleges, education of teachers, universities, public school administration, adult education, vocational education and guidance, negro education and foreign education. In addition there are useful itemised lists of proceedings and annotated lists of reports of associations, and, of course, lists of the publications of the Office of Education itself. The space devoted to the subjects falling within the headings "Exceptional Children" and "Psychology" is remarkable. It includes the following among other sub-headings: behaviour and problem cases, gifted children, guidance, heredity, individual differences, learning, measurement, mental tests, personality and character.

THE *Universities Review* for October contains a further contribution to the discussion, begun a year ago, of "What is Wrong with the Modern Universities?" The writer, Mr. P. Mansell Jones, of Cardiff, suggests that "it is our working idea of a university which is wrong". The schemes of study and methods of work lack the elasticity indispensable for meeting the differing needs of individual students, and degree requirements necessitate the pursuit of numerous short courses administered in water-tight compartments. Hence the (alleged) prevalence among British students of an artificial separation between life and work, resulting in indifference to and sterilisation of the intellectual life. In the same issue of the *Review* is a report of a lecture by Sir Josiah Stamp delivered at Princeton University last April on the contribution of academic life to economic problems of the day. Referring to the impression he had received in America of widespread loss of faith in institutions, men, and 'slogans', Sir Josiah exhorted his hearers not to lose faith in the value of striving for intellectual solutions. Not only should economic problems be subjected to strenuous investigation by scientific methods but there is also an economic hinterland and a moral hinterland to every field of specialised knowledge, and this region should be surveyed with confidence by every outgoing graduate.

Calendar of Geographical Exploration

Dec. 5, 1766.—Bougainville's Circumnavigation

Louis Antoine de Bougainville sailed south for the third time in the *Boudeuse*, charged with the commission of ceding the settlement on the Falkland Islands, which he had organised in 1763–65, to Spain, and continuing his voyage across the Pacific. Bougainville returned in 1769, having accomplished the circumnavigation of the globe, the first Frenchman to achieve this. His voyage is of interest because a botanist and an astronomer were taken for purposes of scientific research, an example soon followed by other expeditions, with great benefit to the cause of science. Bougainville discovered many new islands in the Pacific, including the Navigators' Islands in the Samoan group, the Grand Cyclades of the New Hebrides, and Bougainville and Buku Islands in the Solomon group; the strait between the former island and Choiseul is named after him. The simplicity and humour of his narrative of the journey round the world gained great popularity for it.

Dec. 7, 1872.—Start of the *Challenger* Expedition

H.M.S. *Challenger* sailed from Sheerness on one of the most fruitful scientific expeditions ever organised. The British Admiralty and the Royal Society cooperated in organising the voyage, Sir G. S. Nares undertaking the naval command, and Sir Charles Wyville Thomson taking charge of the scientific side. Two traverses of the North Atlantic Ocean were made, and one of the South, the Wyville Thomson ridge being charted. The Pacific and Antarctic were then visited and the *Challenger* returned in 1876 with scientific data which filled fifty volumes published between 1880 and 1895, under the editorship of Sir C. Wyville Thomson and Sir John Murray. Many little-known places were charted and surveyed and the longitude of others was corrected. The contours of the great ocean basins were determined, much new information about deep sea temperatures and about ocean currents was obtained, the structure of coral reefs was investigated and many biological surveys were recorded.

Dec. 10, 1607.—John Smith in Virginia

John Smith set out to discover the source of the Chickahominy River. It was on this voyage that Pocahontas, the little daughter of the great Indian chief Powhatan, saved Smith's life by her pleadings. In the spring of the same year, Smith had accompanied Capt. Newport in an exploration of the James River to the falls at Richmond. In 1608 Smith explored Chesapeake Bay and went up the Potomac to the site of the present city of Washington and up the Rappahannock to where Fredericksburg now stands. Smith's maps of Chesapeake Bay and of the New England coast from Penobscot to Cape Cod are remarkably accurate.

Dec. 10, 1883.—The Masai Country

Joseph Thomson reached Victoria Nyanza after successfully crossing the country inhabited by the Masai, whose fierce exploits had barred the way to Uganda. Thomson had been sent out by the Royal Geographical Society to examine the possibility of taking a caravan through their country. Leaving Mombasa he crossed the Njiri Desert, explored the rift valley and discovered Lake Baringo. In 1878 the same Society had sent an expedition to East Central Africa and when its leader died, Thomson, who was then

but twenty years old, took over the command, crossed the country between Nyasa and Tanganyika and discovered Lake Rukwa. Later, Thomson explored part of the Atlas range. In 1890 he set out from Quilimane and travelled in the regions between Nyasa, Bangweolo and the Zambezi, covering nearly a thousand miles of unexplored country.

Societies and Academies

LONDON

Mineralogical Society, Nov. 1.—**H. H. Read** and **B. E. Dixon**: On stichtite from Cunningsburgh, Shetland. Stichtite is found at the above locality as rose-pink patches, partly replacing chromite in a serpentine rock. Characters determined include $D = 2 \cdot 19$, refractive indices γ 1·559, α 1·543. Probably biaxial. Chemical analysis and discussion of earlier analyses give as the most probable formula $2(Cr, Fe)(OH)_3 . 5Mg(OH)_2 . MgCO_3 . Mg[CO_3 . (OH)_2] . 4H_2O$.—**H. H. Read**: On quartz-kyanite rocks from Unst, Shetland Islands, and their bearing on metamorphic differentiation. Quartz-kyanite rocks occur as vein-like bodies in kyanite-chloritoid-schist, also as blocks scattered over the slopes. They are intimately associated with rocks much poorer in silica and richer in alumina than the normal country rock. The main component of these associated rocks is kyanite, with chlorite, and 'iron ore'. The origin of the rocks and certain general problems connected with metamorphic differentiation are discussed.—**L. J. Spencer**: A new meteoric iron found near Kyancutta, South Australia. A mass of iron weighing 72 lb. was found in June 1932 just below the surface in a sandy paddock, 28 miles east-south-east of Kyancutta. It shows the characters of the common type of medium octahedrites, and is very similar to the numerous masses of iron found around the meteorite craters near Henbury, in Central Australia, 630 miles distant from Kyancutta.—**C. A. Silberrad**: List of Indian meteorites. The places of fall of the 106 meteorites that have been recorded in India since 1795 are located as accurately as now possible, and plotted on a map. Percentages are given for the day and night falls, and of the monthly falls.—**W. Campbell Smith**: Meteoric stones from Suwahib, Arabia. Within 30 miles of Buwah in Suwahib, where Mr. Bertram Thomas found a chondritic meteoric stone in 1931, two other stones were found a year later by Mr. Philby. They closely resemble the Buwah stone and may belong to the same shower. Sixty miles to the south a third stone was found at Umm Tina, near Shanna well. This is a chondrite of Baroti type and differs from the other two, which belong to the Cronstad type.—**Arthur Russell**: An account of British mineral collectors and dealers in the seventeenth, eighteenth and nineteenth centuries (contd.). Sir Charles Lewis Giesecke, born on April 6, 1761, and died on March 5, 1833, was christened Johann Georg Metzler. He wrote the libretto of Mozart's "Magic Flute" (1791) also other operas. In 1794 he began the serious study of mineralogy and travelled extensively. Later he settled in Copenhagen. In 1806 he undertook a mineral collecting trip to Greenland and remained there seven years, amassing a large collection. The specimens collected during the first two years were captured by an English frigate on their way to Denmark, and were brought to Leith, where they were bought by Thomas Allan. On his return from Greenland in 1813 Giesecke landed at Leith and traced his collection to Allan, with whom he became very friendly. In 1814 he was appointed professor of mineralogy to the Royal Dublin Society, which position he held until his death.—**Arthur Russell**: Note on an occurrence of witherite at the Morrison North Pit, Stanley, Co. Durham. Pure, massive witherite fills a fault fissure cutting coal at this pit.—**M. H. Hey** and **F. A. Bannister**: Studies on the zeolites (4). Ashcroftine (kalithomsonite of S. G. Gordon). The pink zeolitic mineral described by S. G. Gordon in 1924 as a potassiferous thomsonite (kalithomsonite) is shown by X-ray and optical data to be an independent species in no way related to thomsonite, and the name 'ashcroftine' is proposed for it. Ashcroftine is tetragonal with cell sides c 17·49, a 34·04A., a unit-cell content about $40[NaK(Ca,Mg,Mn)Al_4Si_5O_{18} . 8H_2O]$, and D 2·61 ± 0·05. The refractive indices (ϵ 1·545, ω 1·536) are much higher than those of artificial potassiferous thomsonites, and the optic orientation is different.—**W. C. A. Guthrie** and **Christina C. Miller**: The determination of rock constituents by semi-micro-methods. The ordinary course of the analysis of an igneous rock can be very considerably expedited by the use of smaller amounts of material throughout, the necessary accuracy of weighing being attained by means of a microbalance. Numerous experiments show that such a procedure is reliable and involves no loss of accuracy.

Royal Meteorological Society, Nov. 16.—**J. Edmund Clark, Ivan D. Margary, Richard Marshall** and **C. J. P. Cave**: The Phenological Report, 1931. 1931 was officially described as 'wet and dull', the emphasis is on the latter; yet it was the tenth successive year with excess of rain, the total being that of eleven average years. A fresh table gives for each of the thirteen districts the number of weeks showing 'decided' and 'excessive' divergence from the average for temperature, rainfall and sunshine. December 1930 and November 1931 were alone much on the warm side; March and September cold. Such short cold spells in spring threw the flower records back half a week and although migrants reached our coasts to date their progress inland was belated. Slugs and weeds, as might be expected, caused exceptional trouble. Thanks to a second broadcast in March 1931 the corps of observers slightly exceeded 600. More would be specially welcome in West Ireland and North Scotland.—**Sir Napier Shaw** and **Comdr. L. G. Garbett**: A new sort of wind rose. In ordinary meteorological practice, for the representation of wind conditions for stations on land or selected areas at sea, figures or roses for the several months are set out on separate sheets. Consequently, anyone who wishes to visualise the sequence within the year has to take note of information on twelve separate pages. Examples are now given of diagrams in which the results for the twelve months of the year are combined without sacrificing the information for the separate months.—**G. S. P. Heywood**: Katabatic winds in a valley. A Dines pressure-tube anemometer was erected in a valley in the Cotswolds, with the vane 15 ft. above the ground. The meteorological station at Leafield was situated 2¼ miles away, and the records of the anemometer of that station were compared with those obtained in the valley. The speed of the katabatic flow was seldom greater than 1 m./sec., when a katabatic flow was taking place, and the temperature records at Leafield showed an inversion on all those occasions. Observations of smoke drift show that katabatic flow may occur in a layer near the ground without influencing the anemometer at 15 feet.

EDINBURGH

Royal Society, Nov. 7.—W. F. Harper: Supernumerary pectoral fins in *Raia circularis*, Loudon. A male sandy ray (length 43 cm.) caught in the North Sea exhibited a very rare abnormality which consisted of two well-developed fins situated ventrally and associated with the pectoral girdle. Each fin measured 8 cm. long. A single bar of cartilage connected with the coracoid by a fibro-elastic band formed the basal support of each fin, and extended two-thirds of its length before articulating with a series of six jointed radialia. The muscular mass of each fin had a double origin from propterygium and coracoid, and was innervated by the third and fourth spinal nerves.—Amy M. Fleming: The innervation of the uterus. In the uterine muscle there is an irregular asymmetrical non-medulated nerve plexus, the fine nerve fibres of which wind round the smooth muscle cells. Three types of nuclei are present on the course of the nerve bundles. There are four types of plexus-forming cells which show a greater affinity for methylene blue than do the surrounding connective tissue cells. In certain of each type of multipolar plexus-forming cells there are granules sometimes joined by very fine fibrils. A connexion can sometimes be traced between a varicose nerve fibre and one of the processes of the nerve cells.—M. H. Fullerton: Development of the olfactory organ in *Protopterus*. The olfactory organ arises as a solid ingrowth of the deep layer of the ectoderm in which the cavity forms by cytolysis. The anterior portion of the originally slit-like opening which becomes the anterior naris lies in the region of definite ectoderm; the posterior portion which becomes the internal narial opening, lies, however, in the region of heavily yolked cells ('endoderm'). *Protopterus* therefore supports the view that the boundary between ectoderm and endoderm is not a sharp line but a broad 'debatable' zone.—S. L. Hora: Development and probable evolution of the suctorial disc in the tadpoles of *Rana afghana*, Günther. A series of developmental stages enables the author to describe the steps in the formation of the ventral suctorial disc in the tadpole of *Rana afghana*. Some of these steps correspond with the final conditions encountered in the tadpoles of other and different species of *Rana*. The whole process is similar to that in the fish *Garra*. It is concluded that the origin and development of the disc of *R. afghana* can be explained as due to a series of small and gradual changes induced by recognisable factors in the environment which necessitated a change of habit on the part of the organism. The change in habit resulted in the modification of the existing structures and in the ultimate production of a powerful sucking disc.—James Brough: Evolution of the catopterid fishes. A detailed description of the hitherto unknown structure of the head of *Dædalichthys* and the description of a new genus *Campylognathus* is given. The structure of all known forms of the Triassic family of catopterid fishes is analysed, and an attempt is made to indicate the directions in which the family evolved. The trends are of two sorts, those characteristic only of this family and a series of major trends which also went on, independently, in other contemporary groups of bony fishes. A consideration of the latter leads on to a discussion of the general principle of parallelism in evolution.—W. H. Lang: Contributions to the study of the Old Red Sandstone flora of Scotland. Part 7. On *Arthrostigma*, *Psilophyton* and some associated plant remains from the Strathmore beds of the Caledonian Old Red Sandstone. Remains of *Arthrostigma gracile*, Dn. and *Psilophyton princeps*, Dn. (including *P. Goldschmidtii*, Halle) from Scottish rocks are described in detail. In the case of *Arthrostigma* the epidermis and stomata, the tracheidal structure of the central vascular strand, and slender trace bundles in the cortex are described. The epidermis, stomata and tracheidal tissue of *Psilophyton* are compared with the corresponding features of *Arthrostigma*. The spines of *Psilophyton* are described in detail. They agree with the spines of the type material from Gaspé. Sporangia and spores associated with the vegetative remains in Scotland also agree with those from Gaspé.

PARIS

Academy of Sciences, Oct. 24 (vol. 195, pp. 685–724).—Paul Delens: The formal operations of the logical calculus.—D. Pompeiu: Theorems of existence for the zeros of holomorph functions.—Maurice Gevrey: Systems of partial differential equations of the parabolic type.—Marcel Brelot: The point singularities of sub-harmonic functions.—Henri Roure: New formulæ for the calculation of special perturbations.—Gustave André Mokrzycki: The longitudinal balancing of aeroplanes.—Emile Sevin: Cosmic radiation. A theory is developed based on the wave conception of the electro-magnetic radiations leading to the expression for the wave-lengths (λ) which can arise, $\lambda = 3 \cdot 95n \times 10^{-13}$, where n represents a series of simple numbers. The results obtained with this formula are compared with those of Millikan and Cameron and those of Sir James Jeans.—R. Wavre: Certain single layer potentials, generators of real and multiform harmonic functions.—L. Goldstein: A new isotopic effect. The theory developed predicts an isotopic effect in Raman spectra, the order of magnitude of which is the same as that observable in the rotation-vibration bands of isotopic molecules.—P. de Fonbrune: An apparatus for manufacturing glass instruments intended for micro-manipulations. The technique described is based on the use of a source of heat, easily regulated, placed under the microscope.—E. Darmois and Mlle. M. Murgier: The influence of molybdates on the rotatory power of xylose. From the study of the variations of the specific rotatory power, evidence of the existence of the compound $NaHMoO_4.2C_5H_{10}O_5$ is obtained. This compound has a much higher optical activity than that of xylose.—A. Travers and Silice: Dilute perchloric acid as an oxidising agent.—Jacques Bourcart: Sediments of the schlier type in Morocco. An attempt at a palæogeographical reconstitution.—J. Malavoy: The Voltaian and Atacoran (Gold Coast, Togo and Dahomey).—H. Lagotala: Preliminary note on the geology of Loutété-Mounié (Gouéris region, in the middle Congo).—L. Clariond: The extension of the ante-Visean movements in Morocco.—Aug. Chevalier and Conrad Kilian: The presence of the Silurian and of a Palæozoic flora between Kaouar and Tibesti (eastern Sahara).—Pierre Lesage: The progressive acquisition of precocity in *Lepidium sativum*. The heredity of the character of precosity in the open air after life under a frame has been preserved for at least eleven generations at Rothamsted, Rennes, Clermont, Valence, Marseilles and Algiers. At Rennes, this precocity has not been appreciably altered in a series of cultures from the first to the eleventh generation. Diagrams are given shewing the curves of growth at Rennes and at Rothamsted from 1929 until

1932.—Ch. Dubois and N. Sollier: The experimental diagnosis of melitococcia in sheep and goats by means of the allergy reaction. An emulsion of *Br. abortus* has proved to be the best antigen for this reaction: by its means sick animals and germ carriers can be detected. All subjects reacting can be considered as dangerous for other animals and for man.

Forthcoming Events

MONDAY, DEC. 5

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Lieut.-Col. C. W. Furlong: "Tierra del Fuego".

UNIVERSITY OF LEEDS, at 5.15.—Dr. E. J. Holmyard: "Chemistry in the Ancient World and the Middle Ages".

WEDNESDAY, DEC. 7

BRITISH INSTITUTE OF RADIOLOGY, at 5—(Thirteenth Mackenzie Davidson Memorial Lecture at the Central Hall, Westminster).—Dr. J. Chadwick: "The Neutron".

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.45.—Discussion on "Protective Adaptations of Animals, especially Insects", to be opened by Prof. E. B. Poulton.

BIRKBECK COLLEGE, at 8.15—(Foundation Oration).—The Right Hon. Lord Macmillan: "The Sense of Values".

THURSDAY, DEC. 8

BRITISH INSTITUTE OF RADIOLOGY, at 5—(Fifteenth Sylvanus Thompson Memorial Lecture at the Central Hall, Westminster).—The Right Hon. The Viscount Lee of Fareham: "Radium as a Therapeutic Agent—The Case for National Control".

ROYAL SOCIETY, at 4.30—(Croonian Lecture).—Prof. Davidson Black: "The Discovery of *Sinanthropus*".

FRIDAY, DEC. 9

UNIVERSITY COLLEGE, LONDON, at 5.30.—Dr. Davidson Black: "*Sinanthropus*" (second lecture on Dec. 12).

BRITISH INSTITUTE OF RADIOLOGY, at 2.30—(Presidential Address at the Central Hall, Westminster).—Prof. F. L. Hopwood.

ROYAL INSTITUTION, at 9—Prof. J. G. Gray: "Gyroscopic Tops and Combinations".

BRITISH INSTITUTE OF RADIOLOGY, Dec. 7–9. Annual Congress at the Central Hall, Westminster.

Research as a Nation's Investment

SOCIAL conventions classify us as workmen, as employers of labour, as professional persons, as people of leisure, or as the 'idle rich'; but there are times when we all seem to be 'in very much the same boat'. In modern politics a man's vote is worth the same as his master's, and we are getting accustomed to the corollary that this implies an equal degree of responsibility in the public regulation of the affairs of both. One of the more important of these affairs is the means of livelihood, and one of the primary duties of the State is to formulate and carry out such policies as will, in a fundamental and broadly conceived way, promote the material prosperity of its citizens.

If world events during the past fourteen years had not already taught us the lesson, those of the immediate past, and indeed of the present, must surely have made abundantly clear how vitally the ordinary individual in a community such as ours depends for his well-being on the industrial condition of the nation. Business men and operatives may be the first to feel the effects of competition and the loss of markets, but sooner or later the 'sheltered' worker, the professional man, and the gentleman of leisure, whether as earners of income or as payers of tax, are caught in the inevitable undercurrent. The first impulse of each is to exert his bodily strength against the tide, and the second to help another to struggle. No doubt the first few men who fell into the sea struggled likewise, until by research and invention means were found to ride instead of sink; so that to-day the sea is a great highway of commerce, and not merely a human grave. All because man was not content only to turn his face towards 'adverse forces', but went to some trouble, and doubtless to some initial expense, to obtain knowledge enough to convert a menace into an advantage.

Whether our pre-history is weak or not, this is what passes through the mind on reading Sir Frank Smith's recent Norman Lockyer lecture of the British Science Guild on "Industrial Research and the Nation's Balance Sheet"*, and on looking for some adequate reflection of its thesis in the debate in Parliament on the Address in reply to the King's Speech. The discourse is an opportune contribution to the nation's discussions, and the

* The British Science Guild. The Norman Lockyer Lecture, 1932: Industrial Research and the Nation's Balance Sheet. By Sir Frank Smith. Pp. 31. (British Science Guild, 6 John Street, London, W.C.2.) 1s.

occasion demands that prominence should be given to hard facts and authoritative opinions concerning the relation which subsists between the organised prosecution of research and the industrial future of Great Britain. In one or other of its aspects the matter has frequently been examined in the columns of NATURE; nevertheless, so vital is its importance, and so convinced are we that the exigencies of the moment are more likely to obscure than to clarify political vision, that we must return to it again and again without apology, and with all the earnestness at our command.

Four references appear to have been made during the debate following the King's Speech to the part which science must play in solving our industrial problems; we could have wished for a wider appreciation of the real position. Mr. Davies said that the fundamental cause of our depression is the failure to re-adapt our lives to the swift-moving changes brought about by science, which is a partial truth, but not a very helpful pronouncement. The Marquess of Dufferin and Ava expressed the hope that the Government would help in every way scientific research, so that the country might be given a start comparable with that which it had in the nineteenth century; perhaps an assumption that such a policy may be taken for granted may explain the noticeable absence of any echo in the Upper House. The Prime Minister, Mr. Batey, and the noble Marquess referred specifically to the hydrogenation of coal, a process which, if commercially successful, would infuse new life into the coal-mining industry and reduce or arrest the importation of petrol.

Sir Frank Smith's discourse contains statements of fact which show generally, and in this specific instance particularly, how profitable such research is. Five or six years ago, the cost of producing petrol from coal by hydrogenation was estimated to be not less than 2*s*. 6*d*. a gallon, whereas to-day it is 9*d*.; what it will be five years hence will depend on many factors, not the least of which is the progress of research. The main product is not just some sort of oil, but a No. 1 grade petrol. Now, petrol to the value of £13,690,000 was imported in 1931, and Sir Frank Smith states that this year the same quantity of petrol may cost us £26,000,000. In the consideration of figures and opportunities such as these, the cost of the research itself is surely of small moment. Nor are results and prospects far different in other directions of industrial research. Millions of workers are now employed in the new industries based directly on scientific research—artificial silk, wireless, the generation and use of electric power, motor transport, and the cinema; recent investigations into the storage of apples—of which we import nearly eight million pounds worth a year—are believed to have led to an increase in the growers' returns by £100,000. One reads here of a former loss of £250,000 in a year which has been reduced to negligible proportions; there of a loss of fifty million pounds a year which awaits its turn for attention.

Every day in 1931 Great Britain imported on the average more than a million pounds worth of food; how much that we paid for was wasted by deterioration before it could be consumed? If home produce is included, and if (as has been stated) such loss approaches twenty per cent, is not the prize worth an enormously intensified national effort? Research means more than the invention of some ingenious mechanical device which captures the imagination, or alleviates an unwelcome personal exertion; it is not served by romancing Press 'stories' in which a slender basis of fact is made the theme of a sensational announcement. Whether its achievements intrigue the public, or whether they can be appreciated only by technicians, the simple fact is that scientific research has proved itself to be one of the pillars of modern competitive industry. What the ordinary citizen so often fails to realise is the part which fundamental scientific research (exemplified by that performed at the universities) and applied technical research (exemplified by that performed by the industries themselves and by such agencies as the Department of Scientific and Industrial Research) is *already* playing in maintaining him with some degree of stability and comfort in that state of life which he has reached. Nor does he properly appreciate the crash—industrial, political, and social—which would necessarily follow the neglect of opportunities to acquire new knowledge of material resources and new power to use them.

It is the business of scientific men and women to explain to others the position as they know it and the future as they see it. To-day it is more necessary than ever that they should strive to show the voter that research is not merely the concern of the capitalist who uses it to safeguard his possessions; not only the concern of the employer whom it helps to use services and materials to the best advantage; not only the servant of the worker, the conditions of whose

labour have, in many cases, been improved out of all recognition; but also the benefactor of the poor, into whose homes it brings much that was formerly reserved for the rich; and the chief hope of the unemployed, whose chance of a job depends so much on the development of new industries. Where industry and research are concerned, we are indeed all 'in very much the same boat'. The bigger and the better we can make that boat, the happier and the safer we shall be.

The Legality of Sterilisation

EARLY this year a Departmental Committee was appointed by the Minister of Health to examine and report upon the information already available regarding the hereditary transmission and other causes of mental disorder and deficiency, to consider the value of sterilisation as a preventive measure, having regard to its physical, psychological and social aspects, and to the experience of legislation in other countries permitting it, and to suggest what further inquiries might usefully be undertaken in this connexion. This Committee, which is still sitting, is not concerned with the translation into action of any recommendation that it may make, but there is in being a small non-party group, the secretary of which is Wing-Commander A. W. H. James, already prepared with a permissive Bill to legalise the voluntary sterilisation of certain mental defectives, and which has been waiting for the opportunity of introducing this during private members' time. Recently this Parliamentary Sterilisation Committee has circulated to both Houses a memorandum which explains its views and gives a detailed account of the Bill that it is proposed to introduce.

This Bill must surely commend itself to biologists, physicians and lawyers, for it is well drafted, deals only with the mentally deficient (a group with regard to the desirability of whose procreation no doubt has ever been expressed by anyone) and it is a sound project in racial improvement. Many will perhaps deplore the fact that this Bill restricts itself to the mentally deficient, and is meant to apply only to England and Wales. It is greatly to be hoped that it will become law, for the present dubiety concerning the legality of sterilisation cannot possibly be allowed to continue. It would seem that the legality of sterilisation of a normal adult is doubtful. Certainly, a number of sane persons are being sterilised voluntarily, considering this the most efficient method of contraception, and being convinced that they should not run the risk of producing a second abnormal child; none of those, so far, has been prosecuted. There is little doubt, however, that it is unlawful to sterilise a defective, yet this is being done, but only in the case of the well-to-do. It is because sterilisation might be regarded as being illegal that it remains, for the time being, a luxury for the rich, since State, municipal and charitable institutions dare not do it.

So it is that the well-to-do, through voluntary sterilisation, are preventing the repetition of hereditary blunders, whilst the poor, who outnumber them, cannot imitate them, even though they would. For this reason, if for no others, it is highly desirable that this Bill, a purely permissive Bill, concerned solely with voluntary sterilisation, shall become a law of the land.

The Scientific Spirit in Education

Education and the Social Order. By Bertrand Russell. Pp. 254. (London: George Allen and Unwin, Ltd., 1932.) 7*s*. 6*d*. net.

THIS brilliant and provocative essay on the relation of the individualistic and the civic or social aspects of education is in the true lineage of Thomas Huxley and Prof. H. E. Armstrong and deals out essentially the same trenchant criticism of our crooked thinking and stupid prejudices in this field, above all on the place of science in education that we associate with these pioneers and their followers. Mr. Bertrand Russell's philosophic temper makes the book a contribution to the theory and practice of education which even his opponents ignore at their peril, and his able analysis of the social aspects of the educational problem, no less than his fair but searching criticisms of many of the weaknesses in our present system, should commend the book to all scientific workers who are concerned with the place of science in the modern State.

Like every other thinker of this age, Mr. Russell sees that the future of civilisation depends on co-operation, not merely nationally but also internationally, and he considers that the most vital need of the near future is the cultivation of a vivid sense of citizenship of the world. He recognises that under the transforming hand of science the world has become one economic unit, although the backwardness of our political institutions and

beliefs lead each nation to impoverish itself by economic isolation demanding competition when co-operation of the human race as a whole is the price to be paid for the resources and productive powers conferred by science. Until the world has become secure as a single economic and political unit, our whole civilisation is in jeopardy and thus the establishment of an international authority sufficiently strong to impose its settlement of disputes upon recalcitrant States is a reform as fundamental from an educational as from other points of view.

The formidable obstacles to such reforms can only be overcome as a result of education: "The cure for our problems is to make men sane and to make men sane they must be educated sanely." Obviously Mr. Russell leans to individualism, but the philosophic outlook leads him reluctantly to concede that politically in relation to the needs of the civic the education of the citizen must take precedence of that of the individual. Doubtless even the philosopher in him finds some satisfaction for this concession in the paradox that while governmental power depends finally on science, the scientific spirit or the frame of mind which facilitates discovery is one which favours change and certainly not *a priori* the beliefs or opinions which the State considers it prudent for the good citizen to hold. Whether or not the conflict thus suggested between the scientific spirit and the governmental use of science is likely to bring scientific progress to a standstill, there are obviously real dangers in the situations which may arise unless a scientific spirit or a willingness to experiment, not usually characteristic of administrators, finds its way into the seat of power in the modern State. The repression of scientific thought, like the repression of individuality, may have powerful and unexpected repercussions; and Mr. Russell's picture of a society in which the educational system has imposed excessive uniformity, governed in consequence by those whose suavity enables them to please the crowd, is less fantastic than might at first appear.

Having conceded the importance of education for citizenship at the present time, Mr. Russell has felt himself at liberty to indulge in his powers of wit and irony; and he has not dealt too gently with the numerous prejudices and superstitions which encumber education to-day and hinder its fundamental task of fitting the individual for life. Such questions as education and heredity, emotion and discipline, the influence of the home versus the influence of school, the place of the herd instinct, sex, patriotism and class feeling in education, he touches shrewdly and does not shrink from pressing home his argument to uncomfortable conclusions. Once again we are reminded that unless the virulence of nationalism can be abated civilisation cannot continue, or that for those contemplating the entry of a profession, the latter part of their education should be spent in acquiring such knowledge as would enable them to pursue their profession with intelligence and breadth of outlook. On the subject of competition he has trenchant remarks to make not merely on the evils of the examination system but also on the related problem of over-education. "Our social structure increasingly depends upon *trained and well-informed intelligence*." "The average citizen cannot play his part in a complicated world unless he is more accustomed than at present to view practical issues as matters to be decided by the application of trained intelligence to masses of fact, rather than by prejudice, emotion and clap trap." How far we are as yet from this position every newspaper reveals daily; and much of the interest with which the communistic experiments in Russia are followed is due to the fact that they represent the trial of an educational system in which the anti-social element of competition has been eliminated.

Education, however, is not governed wholly by utilitarian conditions or, as Mr. Russell points out, the place of science would be much larger. Economic factors bulk large and have varying effects—incidentally, they do not provide the obstacle to raising the school age in England and Mr. Russell's hit at sectarianism goes fairly home, equally with his criticism of the dead hand of endowment. One of the most valuable chapters in the book is that which analyses the dangers attending the growing tendency to propaganda in education. Failure to teach the young to reach correct conclusions wherever possible not only promotes faction and the danger of destructive conflict but also gravely impedes scientific progress as well as retards the development of that invaluable asset in practical life—the ability to reach true conclusions on insufficient data, dependent on the scientific absence of bias and power of hypothetical thought but also on that quality called judgment which even our universities seem largely unable to impart.

Into this attempt to reconcile individuality and citizenship in education, Mr. Russell weaves a good

deal of his own philosophy of conduct. He gives us indeed no detailed programme though he clearly looks to the growth of the experimental spirit, notably in administration, for the toleration of individuality in the scientific State, and this can only come as education becomes more scientific. This reads strangely like General Smuts's plea for the scientific expert in public affairs, and the whole book might equally be regarded as an exposition of that statesman's warning of the dangerous gap between scientific advance and stationary ethical development—a plea for sincere and courageous thinking and an honest endeavour to order our lives and the lives of the community in harmony with modern knowledge and resources.

R. BRIGHTMAN.

British Freshwater Copepods

British Fresh-Water Copepoda. By Dr. Robert Gurney. Vol. 1. (Ray Society Vol. 118 for the Year 1931.) Pp. lii + 238. Vol. 2. (Ray Society Vol. 119 for the Year 1932.) Pp. ix + 336. (London: Dulau and Co., Ltd., 1932.) 25*s.* each volume.

DR. ROBERT GURNEY'S monograph has been eagerly awaited by all copepod workers. It comes at a peculiarly propitious time for Brady's book, esteemed as it was for many years, and still useful, is now definitely out of date, and a very large amount has been done on the subject since its publication. It is fitting that this new handbook should also be published by the Ray Society, for here we can always rely on the combination of the best matter with excellent editing and form. The present work is not only up to the usual standard but also is exceptionally good, as we should expect from the author who, among many other things, is an expert in the study of copepods, not only systematic—although his knowledge of their systematics is very extensive—but also their bionomics, which study is becoming increasingly important.

The publication of this work at the present time is propitious from another point of view, because the Freshwater Biological Association has recently been founded and among the many subjects of study the bionomics of the copepods may perhaps be said to be among the first in importance. In other countries much has been done in this line but there is still much to do and this book with its suggestiveness and its beautiful and accurate drawings (original drawings by the author himself) will go far in helping those in Great Britain to take a leading part in such biological studies. To determine the species accurately is of the first importance in any scientific research of this kind, and there is now no excuse for it to be neglected.

The species of freshwater copepods in the British fauna are well known and it is not likely that new species will be discovered, but many workers are interested in finding new, so-called, sub-species and varieties. As Dr. Gurney truly remarks, "what is most needed now is not search for these new forms and the hasty emission of geographical speculations founded upon them, but painstaking study of variability and experimental breeding".

The book embodies much of the author's own work and shows a wide knowledge of the work of others. Vol. 1 begins with a bibliography of forty-three pages. Then follows the general part with a good historical account of work done in Britain and in Europe, economic importance of copepods, their food, habitat and methods of collecting, distribution, distribution in relation to the origin of the freshwater fauna, classification, genera and sub-genera, species and sub-species, distribution of allied species, external structure and metamorphosis.

The systematic part, occupying about two-thirds of the book, includes the four families of the Calanoida—Centropagidæ, Diaptomidæ, Temoridæ and Acartiidæ. Each species is carefully described and figured with details of all important structures, and, what is peculiarly satisfactory, the development, in most cases worked out by the author. In thus embracing the development in a large number of species the monograph is unique.

The distribution of each species both in Britain and abroad is given in great detail. In a few instances marine species which enter rivers or estuaries are included, such as the coastal species *Centropages hamatus* which is common in estuaries, and *Acartia clausi*, the latter having a distinct estuarine form, physiologically and structurally distinct.

Vol. 2 deals entirely with the Harpacticoida, the most difficult and exacting group of all the Copepoda. Although many workers have occupied themselves with it there still remains much to be done and the systematic part is in a very unsettled state. Dr. Gurney has done much to clear things up and in spite of some opposition wisely remains

faithful to his own interpretations. Unlike the Calanoida, in which many of the life-histories are complete, the Harpacticoida are little known and until the publication of this volume in no case had the sequence of the copepodid stages been fully worked out. Differences in the nauplian stages are very small and in the copepodid stages measurements are unreliable owing to the contractility of the body. The general characters of the Harpacticid nauplius are given in the first volume. In the second the nauplii of *Canthocamptus pygmæus* are described as typical and the copepodid stages of *Canthocamptus staphylinus*, which are precisely comparable to those of a calanoid. The nauplii of other species are described and figured whenever possible.

The distribution of the Harpacticoida offers many interesting problems and there is much work to be done in clearing these up. The author's discussions under the head of bionomics of the separate species are very valuable and in some cases at least tend to repudiate the idea of any influence due to the glacial period.

The descriptions of the separate species as found in Great Britain are full and clear, involving much laborious counting and figuring of spines and setæ, the figures as before being models of what such illustrations should be.

Marine as well as freshwater copepod workers will be greatly helped by this important work and will look forward to the third volume.

The Science of Colloids

Kapillarchemie: eine Darstellung der Chemie der Kolloide und verwandter Gebiete. Von Prof. Dr. Herbert Freundlich. Band 2. Vierte unter Mitwirkung von J. Bikerman umgearbeitete Auflage. Pp. xi + 955. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1932.) 69 gold marks.

PROGRESS in science, like corrosion, is apt to travel along interfaces, and few areas recently brought under the plough of adventurous workers have yielded a richer harvest than the territory between chemistry and physics occupied by the science of colloids. All the tools available in both the classical branches of knowledge are necessary for the exploitation of this field, yet it requires also its own distinctive outlook and skill. The growth of standard works in a new subject such as this is naturally slow, for each worker tends to review the field from a point of view dependent on his special explorations, and in consequence many of the earlier books were partial in their account of the work done and it was difficult to obtain from them a clear and balanced view of the whole subject.

Prof. Freundlich's "Kapillarchemie" has always been largely free from this defect, and with almost uncanny foresight he adopted in the first edition in 1909 the classification which has served for each succeeding edition. The first volume of the present edition, published two years ago, contains the introductory matter on which the subsequent development of the theme depends, and this second volume will appeal more to the colloid chemist who is interested in the practical side of the subject. In it the typical colloid systems—sols and gels—are systematically discussed, and it is very significant that a much larger proportion of generalised statement is now possible, at least for sols, than could be made a few years ago; so that only one-sixth of the total space devoted to lyophobe sols is now required for individual properties, whereas formerly it was necessary to deal with almost every sol singly. The gels and to some extent the lyophile sols are too distinctive in many properties for general treatment.

One of the most interesting recent developments in the study of colloids is the application of X-ray analysis to the constituent particles of sols and to such gels as rubber and cellulose and their derivatives. The research which has been carried out in these directions is ably summarised and illustrated. The same may be said of other modern work; it is, indeed, very satisfactory to find even some of the more obscure memoirs discussed systematically and in proportion.

While the output of work along the main lines continues in ever-increasing volume, there is evidence that some of the less obvious though not less important systems are being studied. Sols and gels in non-aqueous media, in which ionic effects are absent or profoundly modified, smokes, fogs, foams and colloid systems in solid media, all deserve further attention, if only because of their industrial importance. The meagre information available is indicated in this work.

It is perhaps superfluous to add that in style and completeness, this new edition of "Freundlich" easily maintains its place as the foremost textbook of colloid chemistry.

P. C. L. THORNE.

Short Reviews

Chemical Engineering and Thermodynamics applied to the Cement Rotary Kiln. By Dr. Geoffrey Martin. Pp. xv + 244. (London: Crosby Lockwood and Son, 1932.) 31*s*.

THE cement industry, at a time of great prosperity, celebrated the centenary of the discovery of Portland cement by Aspin by abandoning its research association and allowing the scientific staff to dissipate! Whatever the causes that led to this action, it can only be regarded with regret. Every industry sheltered by a tariff or existing as a monopoly has a national obligation from which it cannot escape. The country has a right to buy cement of the highest quality at the lowest price, equal in every way to that available throughout the world, and it is doubtful whether, under modern conditions, fundamental advances can be achieved without the daily aid of applied science.

Amongst the practical problems of the industry those connected with the rotatory kiln stand foremost. Its fuel efficiency is to-day stated to be but 19·2 per cent, the radiation losses 15 per cent. Dr. Martin has prepared what amounts to a research treatise in which he reduces to a matter of exact thermodynamical calculation most of the quantities connected with the rotatory kiln, and sets out data which should enable engineers to design a really efficient kiln.

The book is essentially one for experts, and the mass of data required will need a good deal of sifting and analysis before use, but it is set out so that the task should not be beyond the capacity of any designing engineer, to whom the work will be indispensable. It is of interest that in the clinkering zone only the heat above a temperature of 1481° F. is of value, so that there is an enormous loss when this high grade heat passes up the kiln to the preheating and evaporating zone.

In a final chapter the author describes recent efforts to design kilns of greater thermal efficiency, particularly some methods of preventing these internal radiation losses: he also deals with the flotation kiln which is under experiment at Asheham. The work is a definite contribution to the detailed study of an important subject though it is certainly very difficult to read.

An Introduction to the Theory of Canonical Matrices. By Prof. H. W. Turnbull and Dr. A. C. Aitken. Pp. xiii + 192. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1932.) 17*s*. 6*d*. net.

A SIGN of the present-day tendency of mathematical thought is in the changed character of many of the books now produced. In the last few years almost all new books in pure mathematics have represented one of two main branches—geometry and analysis. Just now, works on algebra are being published in greater profusion, not the old type of algebra reminiscent of such authors as Salmon and Weber, but a newer type in which the fundamental laws of ordinary algebra are not necessarily valid.

A matrix can be defined most simply as the transformation from one tetrahedron of reference (in n dimensions) to another and, when there are three tetrahedra, the transformation from A to B can be compounded with that from B to C into a single transformation from A to C. Quite recently Heisenberg and Dirac have shown that matrices are eminently suited to the purpose of stating and developing the laws of the new quantum mechanics. The authors of the book before us have collected together, with very full references, all the more important investigations on matrices, and now present them as a co-ordinated whole. A central problem is the reduction of a homogeneous quadratic function of n variables to the form

$$a_1x_1^2 + a_2x_2^2 + \quad . \quad . \quad . \quad . \quad . \quad + a_nx_n^2$$

This is possible in $\frac{1}{2}n(n-1)$ ways and, when all the symbols are real, the number of positive a's is the same for each.

Although the book is mainly a compilation, Chap. ix contains a new investigation of the canonical reduction of a pencil of matrices when the determinant of every member of the pencil is zero. Some applications of matrices to projective geometry are given, and others to differential equations and dynamical oscillations. The book is practically self-contained and is intelligible to a reader with ordinary mathematical knowledge.

Hunger and Work in a Savage Tribe: a Functional Study of Nutrition among the Southern Bantu. By Dr. Audrey I. Richards. Pp. xvi + 238. (London: George Routledge and Sons, Ltd., 1932.) 10*s*. 6*d*. net.

DR. RICHARDS' study of the satisfaction of hunger as an element in the organisation of human society has a twofold interest. It is, as Prof. B. Malinowski says in a highly laudatory preface, the first systematic study of the subject in anthropological literature; and it is an originally conceived and at the same time instructive example of the application of the conception of 'function' to the study of the part played by certain biological needs of man in knitting together and determining the form and relations of economic and social units in a given society. Incidentally, it affords the author an opportunity of arguing cogently and pointedly against the predominance of sex in human affairs as interpreted by the psycho-analysts on the ground of the greater insistency of the needs of the human organism in the matter of food—needs which cannot be repressed indefinitely or even for any great length of time.

Dr. Richards, after stating her case in relation to the points of view of psychology and biology, and pointing out the inadequacy of the commonly accepted economic and sociological methods of approach, proceeds to show how among the south-eastern Bantu food—its acquisition, preparation, preservation and distribution—is fundamental, functionally, in determining the organisation and

working of the social, economic and religious systems, imposing on each social group and its individual members an appropriate ritual and code of behaviour. The whole conception has been worked out by the author systematically to its logical conclusions; and lest it should be thought that Dr. Richards has merely added another to 'arm-chair' studies based upon the observations of others, it must be mentioned that she has tested her material thoroughly in the field during over a year's residence among the Bamba.

Petroleum in the United States and Possessions. By Ralph Arnold and William J. Kemnitzer. Pp. xxi + 1052. (New York and London: Harper and Bros., 1931.) 63*s.* net.

THIS volume constitutes the second of a series of four books destined to cover the entire field of petroleum technology, the others being devoted to principles, occurrences external to the United States, and economics. The incentive to this achievement is "the desire to learn the facts of petroleum and the industry . . . without personal prejudice, biassed influence, or preconceived ideas". The task was a gigantic one, as the authors soon found, and if this volume is a foretaste of the others to come (the reviewer is not aware of their appearance in Great Britain yet), then it is truly a *magnum opus.* Even so, it is unwieldy, not so much on account of its bulk of more than a thousand closely printed pages, but of bulk of data.

The plan is to deal with petroleum in productive areas first, giving summarised statements of geology, development, technology and statistics of every field; so to non-productive areas (States) and extra-American possessions. Elaboration, particularly of statistical detail, is overwhelming; one wonders what purpose it all serves. In fact, in so far as this volume is indicative, we are unable to find anything strikingly new or outstanding from the wealth of technical and economic literature already available. If it is a case of geology of petroleum in America, not only is there more than one good modern textbook available, but also the publications of the U.S. Geological Survey and the American Association, to mention only two prolific sources, are easily accessible. If it is statistics or technology, we turn at once to at least half a dozen specialised volumes, and, of course, to the Bureau of Mines. Thus, while one can only marvel at the patience and enormity of labour represented by this particular book, from the point of view of a valued, permanent contribution to science, our reception of it is but lukewarm.

Aristotle. By G. R. G. Mure. (Leaders of Philosophy Series.) Pp. xi + 282. (London: Ernest Benn, Ltd., 1932.) 12*s.* 6*d.* net.

IT is a little more than a year since the admirable translation of the whole corpus of Aristotelian writings was completed under the editorship of Prof. J. A. Smith and Mr. W. D. Ross. It was amazing to think that it had never been done before, but very satisfactory that it was so well done at last. Then we have the full and useful book of Mr. Ross on "Aristotle" and another by Mr. J. L. Stocks on "Aristotelianism". Now Mr. Mure publishes a book which to a large extent combines the merits of both these, and is a model of skilful compression and arrangement. It is not quite easy reading, though very well written, but can be recommended to anyone who, knowing something of philosophy and interested in its general development, desires to see Aristotle's work surveyed as a whole and placed in its true position, in regard both to his predecessors and the subsequent trend of western thought.

Mr. Mure is a Jaegerite in the main, as every one must be, in tracing Aristotle's work back to Plato's, from which it springs, partly by suggestion, partly by criticism. But he treats the particular textual analysis of Jaeger with the caution that any such work demands in detail. The net result is a most enlightening study from which two main conclusions stand out. One, the most obvious, is that we must in future treat the conjunction Plato-Aristotle rather by way of complement than of opposition; the other, the most surprising, that, with his supreme and encyclopædic mind, Aristotle should have made so little of the mathematics which were flourishing in an advanced state around him. "Aristotle and Mathematics" should be the next monograph on the subject; it is the least fully treated in Mr. Mure's volume.

F. S. M.

Respiration in Plants. By Prof. Walter Stiles and Dr. William Leach. (Methuen's Monographs on Biological Subjects.) Pp. vii + 124. (London: Methuen and Co., Ltd., 1932.) 3*s.* 6*d.* net.

IN spite of the importance of respiration as a fundamental property of living protoplasm, there has been for a long time no really general and up-to-date treatment of the subject from the point of view of the botanist and of the non-specialist reader. The present authors have treated the subject particularly from this point of view. They have attempted to indicate the principles underlying modern studies of plant respiration rather than to present a complete summary of recent researches.

While no doubt opinions may differ as to whether the authors have chosen the best examples to illustrate the arguments, there can be no question that on the whole they have succeeded in their object of providing a readable and understandable treatment of a complex subject. They first discuss the respiration of plants in air; secondly, anærobic respiration; and thirdly, the mechanism of respiration. The third of these chapters is naturally the one offering the greatest opportunity of development. It reaches its highest levels, perhaps, in dealing with the bearing of sugar structure on the availability of hexoses, in discussing the rôle of cytochrome and in summarising Blackman's scheme for the respiration of apples.

Atomic Physics and Vital Activities*

By Sir F. GOWLAND HOPKINS, P.R.S.

THE success of the two discussions held during the current year has justified the policy which decided that such discussions should be organised from time to time. In particular they are valuable when they tempt distinguished workers from abroad to visit the Society as contributors to debate. In the discussion on the structure of atomic nuclei opened by Lord Rutherford, the revelation of new experimental results and of their great significance gave a dramatic character to the meeting. The atomic nucleus for a long time had seemed to be an impregnable fortress; but missiles of high destructive power have been gradually contrived by almost magical skill in the army of attack, and the fortress, in spite of its formidable potential barrier, is crumbling.

It is interesting for the spectator to realise how much is learnt by the commanders of the attack from the nature of the missiles (parts of itself) with which the fortress replies to the bombardment. One cannot help recalling the sense of progressive accomplishment which was conveyed in Lord Rutherford's opening address, as for example when he dealt with the nuclear origin of the γ-rays. Nor can one forget moments of actual excitement as when, recalling a twelve years' old prophecy of his own respecting the probable existence of neutrons, he referred to Dr. J. Chadwick's recent success in producing these entities (of which the mass is unity and the charge zero) by bombarding beryllium with α-particles from polonium. Exciting again was the account of the striking results obtained also in the Cavendish Laboratory by J. D. Cockcroft and E. T. S. Walton, who constructed an apparatus capable of providing a steady stream of protons, of energy up to 600,000 volts, and successfully employed the stream in the disintegration of the lithium nucleus.

It is not unjustifiable to say that before the moment of Cockcroft and Walton's success, man did not know how to release atomic energy on his own initiative, whereas now, though doubtless in a limited sense, he possesses that power. At the same time, the phenomenon of transmutation seems to be at hand in full reality. The occasion of this discussion cannot fail to stand out as of much significance in the annals of the Royal Society and in the history of Great Britain's contribution to science.

The second discussion dealt with the growth of knowledge at a different level of present accomplishment; but with phenomena that are very significant. It was concerned with recent studies of the nature and properties of those highly active catalysts—the enzymes—the presence of which in each living unit converts a system, which without them would be static, into an organism which is so characteristically dynamic. Anyone who reads in succession the records of these two discussions as found in our *Proceedings*, will perhaps be tempted to wonder how soon, if ever, intellectual concepts, based upon the phenomena which were the subject of the first, are fated to invade, and perhaps revolutionise thought in the great field of which the second covered part. Will the data of atomic physics ultimately illuminate the processes of life?

At present we know nothing to suggest a certain answer. I have indeed met not a few who had a strong *a priori* conviction that life, in some way, in some limited sense at least, makes use of atomic energy; that such ability might indeed be the special stamp of life. Some twelve years ago a distinguished Dutch physiologist, the late Prof. Zwaademaker, thought he had proved that the weak radioactivity of potassium is an indispensable stimulus to certain vital activities; but the importance of this influence would seem to be at most very small. Even Zwaademaker did not hold that it conditioned life. Its radioactivity is certainly not the main reason for the indispensability of potassium in living systems.

Certain recent experimental studies, however, seem to have proved that living tissues may be the seat of radiations able to produce effects at a distance, and to suggest that certain activities in one cell of a tissue can thus influence activities in neighbouring cells. It was claimed some time ago by Gurvitsch, a Russian biologist, that when growing cells divide they emit rays which accelerate the processes of division in other cells. The existence of these mitogenetic rays, so called because of the claim mentioned, met at first with general disbelief, and a year ago I might have been disinclined to mention the subject; but work by many during the last year seems to have brought satisfactory proof that chemical reactions in living tissues are indeed accompanied by radiations, and events in one cell may thus influence other cells without material transmission.

The phenomena as described are doubtless related to that of chemiluminescence which many non-biological reactions display, and may perhaps have affinities with the emission of more intensive radiations by specialised cells in the luminiferous organs of animals or by luminiferous bacteria. The much more general invisible radiations under reference have been now studied by physical methods. Their emission from active cells has been (it is claimed) demonstrated by means of Geiger's counter; their wave-length measured, and by methods which I must not stop to describe, their specific spectra in various cases duly mapped. It has even been claimed, for example, that a characteristic spectrum of a radiation from a tetanised muscle is identical with that yielded

* From the anniversary address to the Royal Society, delivered on November 30.

in vitro by a reaction (the breakdown of creatin phosphate) known to occur in active muscle.

Many published statements of this kind must be received with hesitation until fully confirmed; but that activities in living cells may be accompanied by radiations recognisable by physical means is now, I think, a fact which is proved. This alone will certainly lead to many fresh lines of inquiry. It is not yet proved, however, that the phenomena as described are of fundamental importance, or even that they associated with all forms of life.

What, on the other hand, we do know for certain, is that in all living systems in which dynamic events have been adequately studied, the influence of colloidal catalysts is found to be dominant. These catalysts ('enzymes' if you will) exert a specific control over complex chemical reactions, of which the exact co-ordination in time and space is one of the primary characteristics of an organism. It is, I think, difficult to exaggerate the importance to biology, and I venture to say to chemistry no less, of extended studies of enzymes and their action. Of the chemical reactions displayed in an organism few, if any, proceed uncatalysed; while they are reactions so completely and harmoniously organised that all are maintained in complex dynamic equilibrium. If chemical thought is to function with effect in helping towards a description of living systems, it must dwell especially on this chemical co-ordination which, like other aspects of organisation, illustrates that subservience of parts to the whole which characterises an organism.

The organising potentialities inherent in highly specific catalysis have not, I believe, been adequately appraised in chemical thought. The concentration of a catalyst or, alternatively, the extent of its active surface, will determine the velocity of changes due to its influence, but highly specific catalysts determine in addition just what particular materials, rather than any others, shall undergo change. In this respect they are like the living cell itself, for they select from their environment. Finally, the specific catalyst, in virtue of its own intimate structure, determines which among possible paths the course of change shall follow. It has directive powers. Even in a cell juice, or in an extract from living tissues from which all cell structure is absent, experiment has shown that a group of contributory reactions, including syntheses, may proceed in due and just sequence and so lead to the same end result as is normally reached in the intact living system. A striking degree of organisation may indeed be attained in such preparations under the directive influence of the more soluble enzymes derived from the cell or tissue. Much more then must a structured colloidal system, like the intact cell, in which a number of catalysts with such controlling powers are present in circumstances exactly adjusted to a final result, be one in which reactions are conditioned and organised to a high degree without the aid of unknown or any other influences.

I do not expect that all will feel able to admit as much as I myself would like to claim, namely, that the control of events by intracellular enzymes, exerted in the specialised colloidal apparatus of the cell, by itself secures the status of the cell as a system which can maintain itself in dynamic equilibrium with its environment. I am not denying for a moment that the cell has esoteric qualities which may call for organising influences of a greatly different kind; exerted maybe at some higher level. It is at any rate sure that the inter-related activity of highly specific catalysts represents a notable device of Nature which has supported during the course of evolution those dynamic manifestations which characterise living things.

Prof. R. Willstätter, together with members of his school, has done much to advance our knowledge of these agencies. I have sometimes heard it suggested that the advance in question, from a chemical point of view at any rate, represents a relative failure, apparently because no enzyme has yet been isolated in a state to conform with the classical criteria of 'purity'. If this be the reason for any suggestion of failure, there is surely some misunderstanding. Isolation, individualisation and purity are words which, if used at all in this domain, may well need to be given meanings differing not a little from those which are applicable in classical organic chemistry. Few will doubt to-day that the specific influence of a catalyst is due to its specific structure. All indications, however, point to the circumstance that the active structure of an enzyme is supported by a colloidal 'carrier' which stabilises it. It is indeed likely that in very many cases, if not in all, the active catalytic mechanism is a specific configuration at part of the surface of a colloidal particle, or, alternatively, part of a structural surface in the histological sense. If so, we should no more expect to isolate them in a pure state than so to isolate the active areas on a catalytic metallic surface.

It is true that enzymic activity may be displayed by agencies which are not all strictly of one type. It is not unlikely that in certain cases the specifically active groups may be inherent in the structure of a complex but relatively stable molecule, such as that of an exceptional protein. Cases are known indeed in which a protein many times recrystallised retains specific enzymic activity; in one such case at least it has been shown that the protein structure can be to a large extent destroyed without disappearance of the activity. Crystallisation in such a case does not yield an entity which would reveal its active structure to the ordinary methods of organic chemistry. What is essential for enzyme studies at their present stage is an assurance that a single entity alone is responsible for this or that observed activity. To this end the technique developed by the school of Willstätter has greatly helped. While we are waiting for the knowledge which may ultimately yield, on lines acceptable to current chemical thought, a method for characterising these exceptional entities as

units, the actual configuration which confers activity on this or that enzyme can be, and in many cases no doubt soon will be, determined by indirect methods.

I would like now to illustrate a little further the nature of current progress in animal biochemistry by a reference to investigations dealing with related, but somewhat different aspects of control of dynamic phenomena in living tissues.

From the researches published during the year I might select many to show that efforts to disentangle the complexities of these phenomena can in their own way be as profitable as any branch of chemical endeavour. I think it will be more useful, however, to refer more particularly to one research which is typical of many in respect of its methods and its success. In this the investigator approached on new lines a fundamental problem which for the last sixty years has been the subject of speculation, and no less of experiments which up to a point were informative. The problem was to discover the nature of the final chemical steps which lead to the production of urea in the animal body. That the mammalian liver can convert ammonium carbonate into urea has been many times experimentally proved, and it is equally sure that ammonia and, of course, carbon dioxide are continuously produced in metabolism. Therefore most of us have long been content to believe that urea arises by the direct removal of the elements of water from the molecule of ammonium carbonate.

That urea does indeed arise in the liver by a synthesis from ammonia and carbon dioxide remains certain; but the research under reference, brilliantly carried out by Krebs, of Freiburg-im-Breisgau, has shown that its production is on no such simple lines as those mentioned. It calls for a mechanism involving a most interesting interplay among activated molecules. The facts as revealed have just that degree of unexpectedness—if I may use the phrase—which was to be expected in a biochemical phenomenon. I often find myself compelled to assert that though biochemical events are, of course, limited by chemical possibilities, they are not safely to be predicted by chemical probabilities, even when these are strong. That is why experimental biochemistry must remain an independent scientific discipline.

The essential results of Krebs's research include consideration of the molecular structure of three biological substances: ornithin, citrullin and arginin. In the presence of ammonia and carbon dioxide, and when activated by agencies in the hepatic tissue, ornithin is converted into citrullin which, as a ureido-acid, already carries the carbamide structure. Urea does not arise directly from this, however; another stage intrudes. Citrullin takes up another molecule of ammonia (with elimination of water as at the first stage) and the structure of arginin with its guanidin grouping is thus established. Now arginin is the normal substrate for the well-studied and very active hepatic enzyme, arginase; and under its influence the guanidin group is hydrolised. Urea thereupon splits off from the arginin molecule and ornithin is reproduced. The sequence is then re-established.

Urea is thus produced continuously from the ammonia which arises in the deamination of the amino acids of protein, and from the carbon dioxide of metabolic oxidations in general, but on lines which may seem strangely complex. It would be too much to say at present that this is the only line of origin for urea in the body, but we know now that it is the main line. In maintaining the sequence of reactions, ornithin can function in minute amounts; acting therefore essentially as a catalyst. The nature of the relations involved in this mechanism is characteristic of the living cell.

In another respect this example illustrates the nature of current biochemical studies. The data were obtained by the methods of micro-analysis and only a few milligrams of hepatic tissue were employed in individual experiments. Yet the results were consistent and reproducible and experimental errors well under control. The high accuracy to be obtained in ordinary organic analysis by micro methods is now well recognised, but it is becoming clear that technique is so developing that kinetic studies can be made equally accurate on a similar scale. To studies of living systems this offers advantages which cannot be overestimated.

One further point: it is becoming more and more a matter for confidence that when tissues with cells intact are quickly removed from the animal after its death and placed straightway in a fluid medium of carefully proved adequacy, it only remains to provide an adequate supply of oxygen which shall reach each unit of the tissue, to secure the continuance of the events which had been proceeding *in vivo*. Indeed we are gaining sufficient knowledge of the requirements of such excised tissues to justify the claim that the course of metabolism observed in them during extensive periods of survival need differ in no way from the normal.

We can proceed, then, from the study of tissue extracts in which it is easy to deal with the kinetics of isolated reactions, each determined by its appropriate catalyst, to studies of other tissue extracts, made with discrimination, in which the progress of a variety of reactions retains not a little of the organisation which characterised them during life, and thence to other studies in which we follow the kinetics of reactions controlled by the intact and still living tissues or cells. Thus and otherwise has biochemistry escaped from the dilemma voiced in earlier dogma, namely, that since chemical methods must at the very moment of their application convert the living into the dead, they can do nothing to elucidate the dynamic events of life. The escape is more real than may seem on a superficial view, and especially real perhaps to those who are themselves applying modern chemical methods in the biological field.

Forests and Stream Flow

THE effect of the action of forests in conserving water supplies and regulating the flow of water in streams and rivers, whilst preventing erosion in mountainous countries with consequent disastrous floods, has been under discussion for several centuries. Attention was directed to this important matter in an article entitled "Forests, Climate, Erosion, and Denudations" in NATURE of April 4, 1931. The opinions commonly accepted by foresters and many engineers are to the effect that forests are beneficial (1) by retaining and storing water in the humus layer on the forest floor and allowing it to percolate gradually into springs and streams, thus retarding a rapid run-off; (2) retarding the melting of snow in the spring and thus prolonging the run-off from this source; (3) increasing precipitation; (4) preventing erosion on steep slopes. It may be admitted that direct proof of the actual effect of disafforestation of the catchment area of a river on the future water level of that river based on a prolonged series of measurements, has been so far wanting. But the ultimate results, both to the catchment area and the plains country below should reafforestation not take place, cannot be called in question. Europe itself, along the shores of the Mediterranean, and many parts of India offer numerous illustrations of the aftermath of reckless forest denudation, followed by the drying up of water supplies.

In a paper entitled "Forests and Stream Flow" delivered before the American Society of Civil Engineers at its annual convention in Yellowstone Park on July 6, 1932, Messrs. W. G. Hoyt and H. C. Troxall call in question, from the engineers' point of view, the usefulness of forests in maintaining and regulating water supplies. They base their conclusions on the following. An experiment by the United States Forest Service and the U.S. Weather Bureau was conducted from 1910 until 1926 on two contiguous tracts of land in Southern Colorado (Wagonwheel Gap area) of 222·5 and 200·4 acres respectively, having almost identical geographical, topographical and meteorological conditions. The forest cover in both areas was representative of the Rocky Mountain area as a whole. In 1919 the smaller area was disafforested and the slash burnt in 1921. By 1926 the area had become recovered by a growth of grass, herbs and aspen shoots which had reached a height of three to six feet. Throughout the period, accurate measurements of the run-off and meteorological observations were recorded.

A distinct investigation on stream-flow measurements was begun in 1916 under the auspices of the U.S. Geological Survey, in co-operation with the State of California and the County of Los Angeles on certain areas in California. In August 1924 a forest fire burnt some of the areas under observation, and one of them, Fish Creek, was selected to establish the effect of the fire and resulting disafforestation on the discharge of this creek. A new growth appeared over the area burnt, and by the autumn of 1930 it is said that little evidence of the fire remained, though a different plant association had developed.

The investigations recorded by the authors, and the deductions therefrom, are therefore based in the first case on the observations of seven years (1920–1926) and in the second on six years (1925–1930). It is impossible to do more than glance at the conclusions arrived at from the records and data, which are most ably dealt with in this monograph. They are, however, sufficiently startling to require more detailed investigations on the same lines and will merit careful consideration in many parts of the British Empire where forests, agriculture and commercial interests are so inextricably interwoven. Briefly, the authors hold that forests do not conserve the water supply; that the increase of run-off is not confined wholly to flood periods; that after disafforestation in the Wagonwheel area there was an increase of forty-six per cent in maximum daily discharge; that the belief that forests or vegetation covering will increase the summer run-off and shorten the low-level period through the exercise of storage functions is a fallacy, so far as the records on the two above widely differing areas are concerned. Further, that coincident with the increase in the summer run-off there was an increase in the average summer minimum and the period of low water run-off was considerably shortened; disafforestation made no appreciable change in the low flows which occurred during the winter in the Wagonwheel area.

The authors, who are hydraulic engineers, state that they are lovers of the forest, but in the interest of water supplies and the maintenance of water supply levels, they consider that "If the small growth that springs up immediately after disafforestation" (though this is not the case in all countries) "or denudation exercises practically the same effect as forests in reducing normal flood crests and in preventing erosion without the detrimental effect which forest cover is shown to have on annual flow and flow during the summer low-water periods—then in basins where shortages in water supply are becoming critical or where abnormal expenditures have to be made to augment water supplies, the maintenance of forests or reafforestation for the 'conservation of water supply' may have an effect exactly opposite to that desired."

The investigations, which have been carried out in so liberal a spirit by the United States, are of the greatest importance; and they certainly put a question mark to assumptions which have long been held. It is, however, difficult to believe that foresters and many others who have studied this matter will be able to accept all the deductions of the authors when they are based on records of so short a period as six to seven years.

Obituary

DR. WILLIAM PATTEN

DR. WILLIAM PATTEN, who died at Hanover, N.H., United States, on October 27, aged seventy-one years, will be remembered for his numerous contributions to our knowledge of the earliest fossil fishes, which are generally known as Ostracoderms. After graduating as B.Sc. at Harvard in 1883, and as Ph.D. in Leipzig in 1884, he studied at the Naples Zoological Station; and in 1886–89 he was assistant in the Lake Laboratory, Milwaukee, Wisconsin. He was then professor of biology in the University of North Dakota for four years, and in 1893 he became professor of zoology in Dartmouth College, Hanover, N.H., where he remained until his retirement in 1931.

Dr. Patten's researches on the existing *Limulus* and on the fossil Ostracoderms led him to formulate the theory that primitive arachnids were the ancestors of the vertebrate animals. In 1912 he elaborated this theory in a volume entitled "The Evolution of the Vertebrates and their Kin", which was illustrated with his own beautiful drawings. His facts and arguments, however, failed to convince other zoologists and palæontologists, and he accordingly proceeded with astonishing energy to collect new fossils which might illustrate the subject. He prepared the fossils with great skill and patience, and published a series of valuable papers which are filled with original observations. In the province of Quebec, Canada, he found the first specimens of the armoured *Bothriolepis* showing the tail and median fins. In the island of Oesel, Estonia, which he visited on three occasions, he collected numerous other Ostracoderms in a remarkable state of preservation, including new genera and species which still remain to be described. A. S. W.

PROF. A. BOSTOCK HILL

PROF. BOSTOCK HILL, who died on November 5, was educated at King Edward's School, Birmingham, and pursued his medical studies partly at Queen's College—at that time the Birmingham Medical School—and partly at Edinburgh, and he also obtained a medical degree at Giessen. The early part of his career was directed to chemistry and he became public analyst to the county of Warwick and afterwards, in 1879, professor of chemistry in Queen's College. Two years later he was appointed professor of hygiene in Mason College, and then in the University of Birmingham, when this was created in 1900. The whole of his life thereafter was spent in public health administrative work, and he held several appointments under various authorities.

Bostock Hill contributed many useful publications of public health interest, and wrote on the purification of sewage, water filtration, and the spread of scarlet fever by milk. In public lectures and addresses he dealt with such varied subjects as the history of sanitary development in Great Britain, the evolution of the county health department, and the relation of voluntary effort to State authority in sanitary and social reform.

Bostock Hill possessed considerable gifts as a teacher, and his lectures will long be remembered by his students. Since his retirement from Birmingham, he had been a valued member of the Board of Studies in Hygiene of the University of London. A sound administrator, a shrewd man of business, and an attractive personality, he will be missed by a large circle of friends. R. T. H.

WE regret to announce the following deaths:

Mr. Bernard Hobson, formerly lecturer in geology in the University of Manchester, secretary of Section C (Geology) of the British Association at Sheffield in 1910, on December 3, aged seventy-two years.

Prof. Marco Th. Lecco, emeritus professor of chemistry in the University of Belgrade, on November 4, aged seventy-nine years.

Canon John Roscoe, an authority on the ancient customs of the Baganda and kindred tribes, on December 2, aged seventy-one years.

Electric Supra-Conduction in Metals

THE account given by Prof. J. C. McLennan, in our Supplement this week, of the discussion at the York meeting of the British Association on electric supra-conduction in metals, is most useful as it shows the progress made both by experiment and theory in elucidating this, at least at present, marvellous phenomenon. As soon as Dewar had succeeded in producing liquid oxygen on a large scale in 1892, he and Fleming made an elaborate research to find out how the resistance of metals varied at very low temperatures. They were led to the conclusion that at temperatures near the absolute zero the electric resistance of pure metals would be very small or even zero. Twenty years later, Kamerlingh Onnes, when experimenting with liquid helium, discovered that, when mercury was cooled down to about 4·2° K., it became suddenly and abruptly what is now called a supra-conductor. At and below this temperature it offers no measurable resistance to an electric current. The flow of electrons round the circuit is practically unimpeded. The importance of this from

the electrical engineering point of view was at once appreciated, for if resistance were annihilated, huge amounts of power could be transmitted great distances by very thin wires. Practical applications, however, are still few and engineers await the further elucidation of the phenomenon by physicists. The action of a magnetic field in delaying the appearance of supra-conductivity wants further explanation. The experiments with direct and alternating currents seem to justify the conclusion that a polarisation or orientation phenomenon of some kind is involved in the production of the supra-conducting state in metals. The electron lattice theory is a promising one but in order to verify it a further study of the conductivity of single crystals at very low temperatures is necessary.

Sir Thomas Purves

THE retirement at the end of last month of Col. Sir Thomas Fortune Purves from the post of engineer-in-chief to the Post Office came after ten years of unparalleled development in the art of electrical communications. During his term of office, he had to decide whether the future of telephony in Great Britain was to be manual or automatic. His decision to adopt the Strowger step-by-step automatic system has been proved by experience to have been of great benefit to the country. His pleasing personality was of great value in the development of international telephony. At the conclusion of the War, everything was favourable for the establishment of an extensive European system, provided that national boundaries could be disregarded. The problem therefore was one of politics rather than of engineering, and it was in this field that Sir Thomas's great gifts as a diplomatist had full play. The disarming charm of his manner, his wit and geniality broke down all barriers. In 1924 he met the representatives of the German administration at the Hague and was successful in persuading them to come to the first international telephone conference which took place in April of that year. Since then, conferences of the C.C.I. (Comité Consultatif International) have been held every year. The retirement of a figure of the type of Sir Thomas Purves from these international deliberations will be very seriously felt throughout Europe. When appointed engineer-in-chief in 1922, he prophesied that the coming ten years would see many remarkable developments—such as full intercommunication between the telephone systems of Great Britain and the United States—all of which have been duly accomplished. Great Britain has become the switching centre through which Europe and America communicate with each other and with the British Dominions. No radio centres in the world are comparable in magnitude with the Post Office transmitting centre at Rugby and receiving centre at Baldock. Sir Thomas is one of the most popular members of the council of the Institution of Electrical Engineers, of which he has been president. We hope he will be able to do equally valuable work for many years to come. His successor at the Post Office is Lieut.-Col. A. G. Lee, chairman of the Radio Research Board.

John Phillips and the Geology of Yorkshire

THE annual meeting of the Yorkshire Geological Society was held at Leeds on November 19. The president, Mr. T. Sheppard, took as the subject of his address the work of John Phillips, the pioneer of Yorkshire geology. As a nephew and companion of William Smith, Phillips had unique opportunities for applying the principles of stratigraphy, and his first book on the subject, "Illustrations of the Geology of Yorkshire. Part 1, The Yorkshire Coast", appeared in 1829 and went through three editions; but of Part 2, "The Mountain Limestone District", there is only one edition, 1836. His other book, "The Rivers, Mountains and Sea Coast of Yorkshire", is of a more popular type and includes an account of the "Ancient Inhabitants of the County". Both show his genius for conveying much solid and original geological work in eminently readable form and also his skill as an artist, the illustrations of scenery and fossils alike being from his pencil. It may here be mentioned that Phillips's fossil types, preserved in the York Museum, of which he was long the curator, have recently been carefully labelled and set out for study by Mr. S. Melmore. While at York, Phillips was one of the founders of the British Association, and Mr. Sheppard mentioned an occasion when he astonished the members by giving, without preparation, a surprisingly complete summary of the year's advances in all branches of science. His later work at Oxford and his well-known "Manual of Geology" were briefly mentioned, but Mr. Sheppard promised that when his address was published it should include a complete bibliography. The task of compiling it could not be in more capable hands.

Prof. Max Weber

IN NATURE for December 9, 1922, there was published a letter of congratulation that had been sent by British zoologists to Prof. Max Weber, of Amsterdam, on the occasion of his seventieth birthday. Of the thirty-five who signed that letter, only twenty-five now survive, and these repeated their congratulations on December 5 last, when the distinguished Dutch zoologist completed his eightieth year. Prof. Weber, who has been a foreign member of the Linnean Society of London since 1898, also received a letter of congratulations from the council of that Society. In the last ten years, Prof. Weber's record of work would have done credit to the vigour of a man of half his age. He has brought out a second edition of his monumental textbook, "Die Säugethiere": he is still producing the successive volumes of the "Fishes of the Indo-Australian Archipelago", in collaboration with Dr. de Beaufort; and the reports of the *Siboga* expedition, written by contributors all over the world, continue to appear under his editorship with a regularity that editors of reports of less important expeditions may well envy.

The British Dyestuffs Industry

THE third report of the Dyestuffs Industry Development Committee on the present position and development of the dyestuffs manufacturing industry

in Great Britain is not characterised by the unanimity of the previous report. While endorsing the general conclusions that the Dyestuffs (Import Regulation) Act is achieving its main objects, that the production of dyes during recent years has been satisfactory, especially taking into account the depressed state of some of the principal consuming industries, and the tribute paid to the extension of the range of products, the quality of the output and the standard of research maintained, as well as the technical and scientific progress, the users representatives dissent from the recommendation of the main Committee that the Act be continued on its present basis for a period of three years. On this point, however, independent representatives on the Committee, Profs. G. T. Morgan and Jocelyn Thorpe, make the reservation that the period of continuance should be five years. They base this reservation on the dependence of the industry upon a systematic application of research and the considerable interval of time which invariably occurs between discovery in the research laboratory of a promising dye and its commercial exploitation.

THE difference of opinion between the users representatives and the majority of the Committee appears to turn on questions of price, the formation of an international agreement and the imposition of a ten per cent tariff. The majority report observes that the effect of the recent agreement between Imperial Chemical Industries Ltd. and the continental makers has yet to be seen, but that there is no reason to anticipate a restriction of the output and activities of the British company. They consider, moreover, that the British makers are still implementing the undertaking to supply at world prices during the continuance of the Act. While the users recommend that the Act should lapse on December 31, 1932, there is no recommendation regarding the tariff, and the recommendation that arrangements should be made for British makers to obtain their supplies of benzene, toluene and xylene at prices corresponding to those paid by their foreign competitors is signed by all members of the Committee.

Land Drainage

THE paper on "Land Drainage in England and Wales", read by Capt. J. C. A. Roseveare, chief engineer of the Ministry of Agriculture and Fisheries, at the winter meeting of the Institution of Water Engineers on December 2, possesses a special interest at the present time by reason of the prominent place occupied by the subject of flood prevention in government and scientific circles, as well as among the general public dwelling in areas subject to inundations as disastrous as those which took place in the Midlands in the earlier part of the present year and in the area of the Don in 1931. The paper commenced with a concise résumé of the origins and constitution of land drainage authorities in Great Britain prior to the passing of the Land Drainage Act of 1930, and proceeded to detail the circumstances attending the institution of the Ouse Drainage Commission of 1925 and the Doncaster Commission of 1926, followed by the Royal Commission on Land Drainage in 1927, the recommendations of which formed the basis of the Land Drainage Act of 1930. The principal feature of this Act was the constitution of a series of catchment boards for the administration of drainage areas comprised within watershed lines to be laid down by the Ordnance Survey Department. The Report of the Royal Commission contained a list of 100 suitable catchment areas, but the Act of 1930 scheduled only 47 for immediate creation. Boards for 46 of these areas, covering 67 per cent of the total area of England and Wales, were actually set up before November 1931.

Catchment Boards

CATCHMENT BOARDS may consist of any number of members not exceeding 31, one member being appointed by the Minister of Agriculture and not less than two-thirds of the remainder by county councils and county borough councils, the whole or part of whose areas lies within the catchment area. As regards the functions of these bodies, Capt. Roseveare went on to state that the special sub-Committee on River Gauging of the Advisory Committee on Water, of which he himself was a member, reported that catchment boards were the proper authorities to undertake the systematic gauging of the rivers of England and Wales, and it advocated these investigations as a necessary preliminary for determining the provision required both for the conservation of water and for the voiding of surplus water in wet periods. Reference was made, in this connexion, to the leading article in NATURE of July 2 and to the discussion on the subject at the York meeting of the British Association in September, which has led to the formation of a special Committee, now sitting, "to inquire into the position of inland water survey in the British Isles and the possible organisation and control of such a survey by central authority". The remainder of Capt. Roseveare's paper was devoted to tabular data and general information, of great value for reference purposes, concerning the various catchment areas and their 'main rivers', with some detailed account of the engineering works recently executed in the basin and estuary of the Ouse.

Geography in Current Affairs

At his inaugural lecture in the chair of geography at Oxford on November 15, Prof. K. Mason, after referring to the development of the School of Geography under his predecessors, spoke more particularly of the geography of current affairs (Oxford: Clarendon Press, 1*s*. 6*d*. net). The subject should entail the study of the earth as the home of man, and a framework of geographical knowledge is an indispensable background in the conduct of human affairs. Many of our present-day troubles he traced to a neglect of the teachings of geography. Much of the guidance that we have for the future comes from a study of the historical past, but to be of use for the future it must be set in the geographical present. The geography of the past,

particularly of prehistoric times, is of less importance to the student than the geography of the world as it is to-day. The geographer can make a definite contribution to the solution of many urgent problems of the day in colonisation, trade, transport and agriculture. Scientific surveys of every aspect of man's environment are much needed and the basis of all this work must be an adequate map. Prof. Mason urged that the appointment of a trained geographical adviser in the government of any country would be invaluable in its development and control.

Lord Bledisloe's Cawthron Lecture

NEW ZEALAND is singularly fortunate in having in its Governor-General, Lord Bledisloe, a keen and distinguished agriculturist, thus representing in the highest governing and administrative circles one of the most important industries of the Dominion. On October 3, Lord Bledisloe delivered at Nelson the annual Cawthron lecture, his address being entitled "A Conspectus of Recent Agricultural Research with Some Reflections Thereon". This is the first time that a Governor-General of a Dominion has delivered within it the chief scientific oration of the year, and as one would have expected, in collating the agricultural research of the past three years, as Lord Bledisloe did in the lecture, the economic importance of agricultural research has been emphasised from an essentially broad though authoritative point of view, thus taking into consideration not only the British Empire, but also other countries. The amount of detailed facts, with commentaries, concerning agriculture which have been assembled into this lecture is scarcely short of amazing. Lord Bledisloe has left no stone unturned in his search for data. Every aspect of agricultural and horticultural research is reviewed and there is scarcely a research department, institute or station within the British Empire which is not considered and its recent work discussed. Other countries outside the Empire, such as Denmark, Germany, the United States, Holland, Finland and others, have been combed for results and duly considered. Apart from the general consideration of horticulture, arable and dairy farming and apiculture, and their more detailed aspects such as the study of the constitution of wool, vitamins, etc., researches in connexion with more specialised Empire products such as sugar and tobacco are also reviewed. The lecture has now been published and may be obtained from Messrs. Whitcombe and Tombs, 3 Addle Hill, London, E.C.4, price 1*s*.

Expansion of the Universe

AT the Friday evening discourse on November 25 at the Royal Institution, Dr. Knox-Shaw discussed the observational evidence for the expansion of the universe. The nebulæ lying beyond our galaxy stretch away into space farther than our present limit of penetration. Most of them can be studied only with our largest telescopes, and for our knowledge of their distances and motions we are indebted largely to the work of Dr. Hubble at the Mount Wilson Observatory. In some forty nebulæ he has been able to detect individual stars, and in a few cases to identify them as belonging to types already known in the galaxy. From the apparent luminosities of these stars he has derived distances for the nebulæ in which they are involved. In all other cases the distances are based on the apparent brightness of the nebulæ themselves. The scale of distance thus constructed is still very uncertain. The absorption lines in the spectra of the extra-galactic nebulæ are shifted towards the red in a way that suggests that they are all moving away from us with velocities which increase with the distance. Whether there is an alternative explanation of these shifts is a question for the physicist rather than for the practical astronomer, but if we assume that they actually indicate motions of recession, we find that the velocities of the nebulæ are proportional to their distances from us, as would be required in a uniformly expanding universe. Hubble's value for the rate of expansion, an increase of 560 km. a second for each million parsecs of distance, must be regarded as liable to revision as further observational material becomes available. A cluster of very faint nebulæ in Gemini, so remote that its light has taken some 135,000,000 years to reach us, has recently been photographed at Mount Wilson, and seems to be moving away from us at the immense speed of 24,000 km. a second.

Slaughter-Houses in Great Britain

THE eleventh Benjamin Ward Richardson memorial lecture was delivered, under the chairmanship of Sir James Crichton-Browne, before the Model Abattoir Society on November 30 by Mr. T. Topping, who chose for his title "The Slaughter-House Problem". He commenced by saying that had local authorities more generally carried out the advice given by Richardson when he founded the Model Abattoir Society fifty years ago, there would have been no slaughter-house problem to-day, and there would have been greater benefit for other public health protective measures. As it is, there is a very real problem owing to the fact that the slaughter-house provisions of the Act of 1847 are still the principal law on the subject to-day. No advance was made by the Public Health Act of 1875, so that many buildings quite unsuitable for the purpose came into existence as private slaughter-houses. The Rural District Council (Slaughter Houses) Order of 1924 gave State recognition to and largely increased the capital value of hundreds of unsuitable buildings that had been erected as slaughter-houses prior to the order. Thus for nearly sixty years, most local authorities steadily increased the financial difficulties of providing for the only effective means of supervision of slaughter-houses and of securing hygienic preparation of carcase meat. According to Mr. Topping, there are only about 110 slaughter-houses in Great Britain where the buildings and arrangements are satisfactory, whereas in a large percentage, complete supervision and inspection is extremely difficult if not impossible. As a solution of the problem, he suggested first that the Ministry

of Health should obtain either directly, or indirectly through the county councils, information as to the condition of all the private slaughter-houses in the country, particularly as to deficiencies in meat inspection and their cause, and secondly, that abattoir provision should be on a county basis, instead of allowing each local authority to have its own abattoir.

Ultra-Short-Wave Wireless Communication

IN his Friday evening discourse at the Royal Institution on December 2, the Marchese Marconi described the important results of his recent investigations into the properties and behaviour of very short electric waves. Numerous distance tests and a few official demonstrations have been given from time to time, and each has proved the availability and practicability of these waves for the purposes of radio communications. Soon after a duplex demonstration over a distance of twenty-three miles between Santa Marghorita and Sestri Levante, the Vatican authorities decided to adopt the new system for telephonic communication between the Vatican City and the palace of the Pope at Castel Gandolfo, a distance of 20 kilometres entirely over land, and screened by intervening trees. In connexion with the establishment of this service, successful tests took place towards the end of April this year; during one of these tests waves had to pass through all the masts and aerials of the high power radio station of the Italo Radio Company at Terranuova. Following a series of experiments with waves of the order of 50 centimetres length conducted between Marconi's yacht *Elettra* and the station at Rocca di Papa, near Rome, the most outstanding result was the successful establishment of communication from Rocca di Papa to Cape Figari, Sardinia, over a distance of 168 statute miles (275 kilometres) on a wave-length of 57 centimetres. All previous distance records of communication by means of wave-lengths less than one metre were thus far surpassed, and it was effectively demonstrated that these very short waves can overcome the supposed obstacle presented by the curvature of the earth, the distance between the two stations being considerably in excess of the optical range. A new technique is thus developed which is bound to extend very considerably the already vast field of the applications of electric waves to radio communications. The new system is unaffected by fog, and offers a high degree of secrecy, by virtue, principally, of its sharp directive qualities.

Radio Equipment for Cross Channel Air Services

IN March 1931 a demonstration was given by the International Telephone and Telegraph Laboratories of radio telegraphic communication across the English Channel on a wave-length of about 17 cm. (see NATURE of April 11, 1931, p. 564.) According to a note in the *Electrician* and the *Electrical Review* for November 18, a somewhat similar equipment to that used in the above demonstration has been ordered by the Air Ministry for use in connexion with cross-Channel flying services. This equipment will be manufactured by Messrs. Standard Telephones and Cables Ltd. in their Hendon factory, and it will operate on a wave-length in the neighbourhood of 15 cm. The oscillations corresponding to this wave-length will be generated by special valves and will be led to the transmitting aerial, which is less than one inch long, situated at the focus of a circular reflector about 10 ft. in diameter. This reflector will be focused on to a similar reflector at the receiving station. The equipment ordered by the Air Ministry will be located at the Lympne air-port, near Hythe, and will operate in conjunction with a similar equipment ordered by the French Air Ministry to be situated at St. Inglevert aerodrome, nearly seven miles south-west of Calais. It will be used for announcing the arrival and departure of aeroplanes that are not fitted with radio, and for routine service messages. An interesting feature of this new service will be the use of teleprinters for both receiving and transmitting messages. In this way typewritten messages will actually be sent across the Channel by radio, thus providing a permanent record at each end. It is expected that the station will be in operation early next spring and its use will relieve the volume of traffic at Croydon and Lympne radio stations very considerably.

Scientific Expedition to Yunnan

IN the spring of 1932 a joint botanical and zoological expedition was sent to eastern Yunnan by the Fan Memorial Institute of Biology, Peiping, starting from western Szechuan and exploring the bordering regions of Szechuan, Kweichow and Yunnan. The party expects to spend the winter in Yunnanfu. The botanical staff will endeavour to explore regions formerly not thoroughly worked over and collect also specimens in the type localities. Besides collecting flowering plants, special attention will be devoted to mosses, liverworts, ferns and other cryptogams. The zoological staff will collect birds, fishes, other lower vertebrates and land shells. News has been received that the party succeeded in penetrating the forbidden territories of Ta-Liang-Shan Lolos, where probably no white man has ever entered before. These Lolos are very war-like tribes. They frequently kidnap Chinese and make them slaves. By a curious chance the present powerful chieftainess is the sister of the military governor of Yunnan, and hence much more enlightened in her view toward the purpose of scientific expeditions. The party was welcomed as honourable guests by the chieftainess. Oxen and pigs were slaughtered in their honour, and an elder of the tribe has been handed over to the district magistrate as the pledge of their safety. As two years ago the lamentable death of the eminent young Chinese palæontologist, Ya-Tseng Chao, at the hands of bandits had cost the district magistrate of Chao Tung Hsien permanent dismissal from office, such precaution is carefully taken by his successor. The party plans to explore the south-eastern part of Yunnan next year.

Popular Science

To apply the term 'popular science' to a book is generally sufficient to make a man of scientific training turn aside distrustfully. This is particularly unfortunate in these days of increasing specialisation, when it is more than ever desirable that specialists should be enabled to follow broad lines of advance in fields other than their own, but the fact remains that most popular science books are 'written down' and simplified to the point of sheer inaccuracy. There is also an increasing body of laymen interested in the advances of science who rightly ask to have accurate though plain accounts of current work. Davy and Faraday showed one way in which both needs can be met: the scientific worker can come from his laboratory and explain his investigations. Faraday's Friday evening discourses at the Royal Institution are still regarded as models of exposition, and it may justly be said that Faraday's mantle has fallen on the present occupant of his post, Sir William Bragg. Sir William's course of Christmas lectures of 1923-24, "Concerning the Nature of Things", forms an admirable introductory volume in a group of four published by Messrs. G. Bell and Sons, Ltd., in a new "Popular Science Series" (4*s.* 6*d.* net each). From that we may pass to "Engines", by Prof. E. N. da C. Andrade, another course of Christmas lectures at the Royal Institution, and then perhaps to Prof. J. Kendall's "At Home among the Atoms", described by its author as "A First Book of Congenial Chemistry", which with its quaint chapter headings and unconventional diction will amuse as well as inform. Finally, there is Prof. Andrade's "The Mechanism of Nature", a more ambitious work for the intelligent reader, surveying in plain language modern views on the structure of matter and radiation. All these books have been published before, but in their new and tasteful 'dresses', any or all of them might well serve to solve the problem of the selection of a Christmas present for a young or an older reader.

Electrically Heated Incubators

THE use of electrically heated incubators is steadily increasing. Some people think that the method is a risky one, as the interruption of the electricity supply even for a short period might involve a failure. We learn from the Electrical Development Association (the E.D.A.) that this risk is negligible. For example, a leading firm of poultry farmers and incubator manufacturers sent batches of eggs in its incubators to agricultural shows. In one case, two batches, 219 eggs in all, were sent to the Royal Show at Southampton. One batch had been incubated for thirteen days and the other for fifteen. After being taken out of the incubators at the farm they were packed in egg-boxes and carried in a loaded three-ton lorry a distance of sixty miles by road to the show. They were then unpacked and placed in the incubator. At the end of the normal periods 209 chicks were hatched. The eggs were out of the incubator for a very much longer period than any interruption in an electricity supply is likely to last. Another case is described where the half-incubated eggs were packed in the ordinary way and sent 240 miles by road and train without any apparent effect on the number of chickens hatched.

Institution of Automobile Engineers' New Journal

THE Institution of Automobile Engineers had its birth in 1898 at Birmingham, as the Cycle Engineers' Institute, and took its present title in 1906, when its headquarters were removed to London. In 1911 it had a membership of 530, while to-day it has a membership of 2,520, with seven provincial centres and a branch in New Zealand. Up to the present, it has only issued leaflets devoted to the papers read and other matters, while the *Automobile Engineer*, published by Messrs. Iliffe and Sons, Ltd., has been considered as its official organ. It has now, however, been considered desirable that the Institution should have its own monthly journal, and the first issue of this has recently appeared. The *Journal* is intended to include advance copies of papers to be read, summaries of the discussions which take place, abstracts of papers and articles from other sources and reviews of books of special interest to members. This is certainly a step in the right direction and one which will be generally appreciated. Last year the Institution formed a Research and Standardisation Committee and appointed a director of research and the first issue of the new *Journal* includes the annual report of the Committee for the year July 1, 1931–June 30, 1932.

Armstrong College Mining Society

THE July number of the *Journal of the Armstrong College Mining Society* has recently been issued. Probably the most important paper in it is one by Prof. Granville Poole and Mr. J. T. Whetton on "Skip Winding", showing how this method is being adopted in a number of German mines, even in certain collieries. It is doubtful to what extent this method of winding is applicable to British collieries, but its use should, no doubt, be carefully considered. It has, of course, been used for many years as the main method of winding in the metalliferous mines of Cornwall, although the authors of the paper appear to have overlooked this fact entirely. It may also be pointed out that they make no allusion to the methods which have been recently tried in Germany of constructing skips of material lighter than steel. Another interesting paper is one by Mr. M. T. Adamtchik on the so-called 'Aeroto' fan, which apparently is simply a multiple propeller fan. Curiously enough, the author makes no reference to the Stoart fan, which was the first type of propeller fan ever employed; it would appear that the fan here described is simply a development of the latter fan. The *Journal* concludes with a glossary of mining terms, with French and German equivalents, which unfortunately are not always correct.

Taxonomy of the Hymenomycetes

THE presidential address of Mr. A. A. Pearson to the British Mycological Society reviews the European

Electric Supra-Conduction in Metals*

By Prof. J. C. McLENNAN, O.B.E., F.R.S.

THE discussion at the York meeting of the British Association on the electric supra-conductivity of metals was opened by a reference to the classical experiments of Dewar and Fleming[1] made in 1893 on the electrical conductivity of metals cooled to very low temperatures by means of liquefied gases, including air and hydrogen. These yielded results suggesting that the electrical resistances of all pure metals would vanish at the absolute zero of temperature.

This suggestion, however, proved to be wrong, for in 1911, Kamerlingh Onnes at Leyden, while carrying out researches at low temperatures with the aid of liquefied helium, discovered that mercury, when cooled down and solidified with liquid helium, suddenly and abruptly at about 4·2° K. became what is now designated as a supra-conductor of electricity. At temperatures below 4·2° K., mercury offers no measurable resistance to the passage of a current. Currents of electricity started in a ring of a metal in the supra-conductive state will continue apparently undiminished in intensity while the metal is in that state. The duration of these persistent induced ring currents seems to be limited only by the length of time the cooling agent, liquid helium, will last. In the course of a lecture on the evening of June 3 last at the Royal Institution on supra-conduction in metals, I exhibited to the audience a closed ring of lead immersed in liquid helium and carrying a current of more than 200 amperes. The current had been started in the supra-conducting lead ring some six hours earlier in the afternoon by Prof. Keesom in Leyden, and *it persisted undiminished in intensity while being* transported in liquid helium by aeroplane from Leyden to London by Colonel the Master of Sempill.

* From a discussion on electric supra-conduction in metals held in Section A (Mathematical and Physical Sciences) on Friday, September 2, at the York meeting of the British Association. Among those who took part in the discussion were Prof. J. C. McLennan, Prof. W. J. de Haas, Dr. W. Meissner and Prof. O. W. Richardson.

SUPRA-CONDUCTIVE METALS

Metals in addition to mercury and lead that exhibit the supra-conductive property if made sufficiently cold are tin, indium, gallium, thallium, tantalum, titanium, thorium, and niobium. The transition temperature for the passing of a metal from the ordinary conducting to the supra-conductive state is not a constant but varies with the metal. For mercury it is 4·22° K., for lead 7·2° K., tin 3·7° K., tantalum 4·4° K., thallium 2·37° K., indium 3·37° K., gallium 1·05° K., thorium 1·5° K., titanium 1·75° K., and niobium 8·2° K.

ALLOYS AND CHEMICAL COMPOUNDS

Some alloys and chemical compounds of the metals also exhibit the supra-conductive property. Copper sulphate, for example, does so, though none of the constituent elements is a supra-conductor. The nitrides and carbides, borides and silicides of several of the metals, such, for example, as those of molybdenum, tungsten, tantalum, zirconium and niobium, are also supra-conductive at sufficiently low temperatures.

The addition of metals of the bismuth group to supra-conductive metals has been found, speaking generally, to raise their transition temperature. Bismuth added to lead raises the transition temperature from 7·2° K. to 8·8° K.; carbon raises that of niobium from 8·2° K. to 10·5° K. Gold

alloyed with bismuth becomes supra-conductive at 1·94° K., whereas neither constituent alone becomes supra-conductive even at the lowest temperatures obtainable.

With pure metals the transition from the ordinary conductive to the supra-conductive state generally occurs within a tenth or at most a few hundredths of a degree. With impure metals, with alloys or with chemical compounds, the transition is not generally so rapid. In the transition stages, in the case of most of the metals the variation of resistance can be readily followed by observing the vapour pressure of the liquid in which the metal is immersed. In the case of liquid helium, a variation in vapour pressure of about 40 mm. of mercury corresponds to about one tenth of a degree centigrade.

Recently McLennan, Allen and Wilhelm, in making a study of various alloys of the silver-tin, gold-tin, gold-lead systems, found three outstanding features to characterise the results. First, in alloys with the supra-conductive elements it was observed that gold and silver produced an effect on the transition temperature opposite to that produced by bismuth, antimony and arsenic. When one observes alloys containing the latter metals, one finds usually a pronounced elevation of the supra-conducting temperature, while in alloys with gold and silver one finds an equally pronounced depression of the supra-conducting temperature. Secondly, it was noted that a binary alloy system composed of a supra-conductor and a non-supra-conductor does not necessarily have a unique transition temperature. Thirdly, it was found that with the alloy systems, silver-tin, gold-tin, gold-lead, the transition temperatures were higher for eutectic mixtures than for chemical compounds of the two metals constituting the alloys. The data compiled in Table I will serve to illustrate these points. The element silver and the compound Ag_3Sn, it will be seen, have not been found to be supra-conductors at any temperature reached up to the present.

TABLE I

Tin-Silver Alloys

Substance	Mixture	Percentage of Tin	Transition temperature
Tin	Pure	100	3·76° K.
Silver and tin	Eutectic alloy	96	3·52° K.
$Ag_3Sn + Sn$	Eutectic alloy	50	3·57° K.
Ag_3Sn + 3 per cent Sn	Mixture	30	2·3° K.
Ag_3Sn	Compound	27	—
Silver	Pure	0·0	—

Mechanical Strains and Thermal Dilatation

The application of mechanical stresses such as those of torsion and tension raises the transition temperature of a supra-conducting metal, but observations made on the thermal dilatation of a lead rod showed no discontinuity when its temperature was lowered as it passed through the transition temperature, 7·2° K., from the ordinarily conducting to the supra-conductive state.

Action of a Magnetic Field

The application of a magnetic field delays the appearance of supra-conductivity and causes it to appear in a metal at a lower temperature than normally.

If a metal in the supra-conductive state be subjected to a gradually increasing magnetic field, a critical field strength is reached when electrical resistance re-appears in the metal. The strengths of the critical fields required for different supra-conductors vary; an alloy of bismuth and lead, for example, at 1·2° K. requires a magnetic field of 20,000 gauss to restore the property of electrical resistance, while metallic thallium at the same temperature requires a field of only 15 gauss.

Since the electrical resistance of supra-conductive metals is zero, no heat is produced when electrical currents are passed through them. Currents of high intensity can therefore be passed through supra-conductive wires of small diameter without melting them. Electric currents of more than 1,000 amperes have been so obtained in wires of small cross-section. The factor that imposes a limiting value upon the current strength is the magnetic field set up in the wire by the current itself. A critical value is reached when resistance is restored to the wire by the magnetic field.

Owing to the fact that metals in the supra-conducting state have no electrical resistance, currents of electricity induced in rings of metals in this state will persist with undiminished intensity so long as the metals remain supra-conductive. So far, it has been found impossible to detect with instruments of precision any diminution in the intensity of ring currents in supra-conductors even after the lapse of a period so long as thirteen hours.

Recently some experiments were carried out

by McLennan, Allen and Wilhelm on the intensities of persistent currents of electricity induced in rings having the same dimensions of lead, tin and tantalum, brought into the supra-conductive state by the use of liquid helium. The currents in the rings were induced by the magnetic field provided by electric currents established in a circular coil of wire placed in turn coaxial with and close to each of the supra-conducting rings. The results of these experiments are represented by the graph shown in Fig. 1. It was found that, for the weaker magnetic fields, equal changes of flux produced currents of equal magnitude in each of the three supra-conductors. The magnitude of the persistent current developed depended not on the substance of the supra-conductive ring but only on its dimensions and on the magnitude and form of the inducing magnetic field.

The case of tin is very interesting, since the values of the current in it agree with those of the current in the others only up to fields of about 25 gauss. For inducing fields higher than this amount the strength of the persistent current dropped off. Above this point, then, part of the ring must have been in a magnetic field, the strength of which had reached the critical value where resistance re-appeared, that is, an inner layer of the ring must have become non-supra-conductive. As the field was increased above this point, one can suppose the outside supra-conductive portion of the ring became thinner and thinner until the whole ring became non-supra-conductive.

The fact that the same flux engenders the same persistent current in different supra-conducting metals having the same size and form follows from an application of the equation

$$L\frac{di}{dt} = \frac{dB_A}{dt} \quad \text{or} \quad i = \frac{B_A}{L}$$

For rings of the same dimensions, the self-inductances would be identical; and in the supra-conducting state the resistances of the three metals would be vanishingly small. Self-induction and zero resistance were the two factors that made the magnitude of the induced current in different supra-conductors the same.

Looking at the matter in another way, we see that the induced currents in the three supra-conductors must be the same since the magnetic field of the persistent current must be equal in magnitude and distribution but opposite in direction to the flux of the exciting field.

Alternating Fields

Since the discovery of the phenomenon of supra-conductivity in metals by Kamerlingh Onnes in 1911, researches in this field have been until recently almost invariably carried out by the use of unidirectional electric currents. No systematic attempt appears to have been made hitherto to investigate the phenomena of supra-conductivity with alternating electric currents of high, medium and low frequencies.

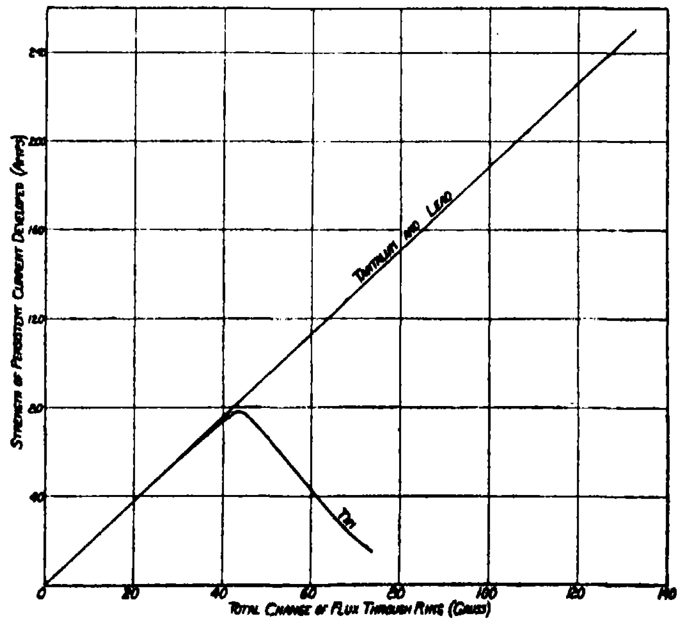

Fig. 1.

Some of the theories[a] put forward to explain supra-conductivity suggest that an orientation of some kind is involved in the production of the supra-conducting state in metals. If this suggestion should prove to be correct, one would expect some modification of the phenomenon for currents of high frequency. It need only be mentioned that all 'orientation' effects are considerably modified in an oscillating field with a time-period of the order of, or less than, the 'time of relaxation' of such orientation. A well-known example is that of the dielectric constant, which rapidly diminishes in value for very high-frequency electric fields. As to 'relaxation times', it will be recalled that in the case of ice, experimental evidence shows

that the relaxation time is of the order of 10^{-4} sec. at 0° C. and rapidly increases as the temperature is lowered.[3] It would not seem unreasonable then to expect to find 'relaxation times' exhibited by metals in the supra-conducting state, provided one used in one's experiments alternating fields of suitable and adequate frequencies. A short time ago an investigation was initiated in this direction by McLennan, and through a set of researches carried out successively with the collaboration of a number of his associates, namely, Niven, Wilhelm, Burton, Allen, Smith, McLeod and others, the work recently culminated in the discovery that such metals as lead, tin and tantalum can be made to exhibit, when in the supra-conducting state, characteristic phenomena that point to their possessing 'relaxation times' roughly of the order of 10^{-7} sec. or 10^{-8} sec.

Absorption of β-Rays by Supra-Conductors

In the first of these researches[4] the absorption of β-rays by a thin sheet of lead was investigated when the lead was gradually cooled from a temperature a few degrees above to a few degrees below the critical transition temperature of 7·2° K. The β-rays used were those emitted by mesothorium and the lead sheet had a thickness sufficient to absorb, at ordinary room temperature, 50 per cent of the β-rays issuing from the mesothorium. In these experiments no measurable variation or discontinuity was detected in the absorption coefficient as the temperature of the lead was lowered through the critical value 7·2° K. The high-velocity electrons from the mesothorium apparently encountered just as much resistance in their passage through the lead with the latter in the supra-conducting state as when the lead possessed the normal conductivity exhibited at the higher temperatures. This investigation gave definite proof that although resistance in the supra-conducting state is zero, or a very low value for currents carried by slow-moving electrons, it is not zero but maintains a normal value for currents carried by high-speed electrons.

Looking at the matter in another way, this result indicates, if the de Broglie wave equation $p = h/mv$ applies, that lead at the lowest temperatures cannot exhibit supra-conductivity when subjected to alternating electric fields with frequencies of the order of 10^{11} per sec.

Photoelectric and Light Absorption Experiments

In a second series of experiments,[5] thin films of lead were deposited on plates of glass and of quartz, sometimes by cathode spluttering and at other times by vaporisation of metallic lead. These films were subjected to a series of decreasing temperatures commencing a few degrees above 7·2° K. and ending at the temperature of liquid helium, 4·2° K. The photoelectric effect and the absorption of visible light were in turn investigated with these films and measurements were taken approximately by steps of a fraction of a degree as the temperatures of the films were lowered. In these experiments no measurable discontinuity was observed in the results of the measurements on the photoelectric effect, or in the results of those on the coefficient of absorption of the light waves when the lead films traversed were passed through the transition temperature of 7·2° K. These results were taken therefore to indicate that supra-conductivity with lead is a phenomenon that cannot be exhibited when electric fields alternating with a frequency approximately equal to or greater than 10^{14} per second are used.

It is clear, however, since supra-conductivity can be brought into evidence by the use of unidirectional fields, that is, with fields of zero frequency, that there must exist some critical alternating field with a frequency between zero and 10^{14} per second, by the use of which supra-conductivity should just be detectable.

Experiments with Electric Fields of Radio-Frequencies

Through the development which has taken place in recent times, it is a comparatively simple matter to arrange combinations of oscillating valve systems capable of providing alternating electric fields with frequencies so high as 10^7 or even 10^8 per second. Some experiments were therefore made with radio fields having frequencies approximating to 10^7 cycles per second and corresponding to a wave-length of about 30 metres. With fields of this frequency, it was thought that the phenomenon of supra-conductivity might appear with lead at a lower temperature than 7·2° K., might even be only partial, or might not appear at all. The experiments[6] and apparatus used, together with the theory applicable, have been

fully described elsewhere and it will suffice to give here only a summary of the results obtained.

It was found that with currents of frequency $1{\cdot}1 \times 10^7$ per second a coil of lead wire showed an abrupt loss of resistance, of relatively large amount, at a temperature that appeared to be slightly lower than the critical temperature 7·2° K. characteristic of the transition to supra-conductivity, found for the same wire with direct current.

In a series of repeated experiments with a coil of tin wire, drawn to a diameter of 0·3 mm., it was found that with direct currents the resistance of the coil began to decrease abruptly at 3·76° K. and disappeared completely at 3·70° K. Experiments with the same coil with currents of frequency $1{\cdot}1 \times 10^7$ per second gave for the corresponding temperatures 3·67° K. and 3·61° K., that is, supra-conductivity did not begin to appear until a temperature was reached that was below the one at which it was complete in the case of the direct current experiments. Further experiments with higher frequencies revealed depressions of the critical transition temperature increasing in amount with the frequency. Extrapolation of the transition temperature – frequency curve, which appeared to be linear for the higher frequencies, gave 10^8 per second for the frequency corresponding to 0° K.

With tantalum wires and with wires of a bismuth-lead alloy, results were obtained similar in character to those found with wires of tin and of lead. Experiments with tin wire coils showed that the observed depression of the critical temperature was not dependent upon the magnitude of the high-frequency currents in the coils and was therefore attributable neither to the heating of the coils above the temperature of the surrounding liquid helium, nor to the effect of the magnetic field of the currents. Experiments with wires of different sizes made with currents of the same frequency showed that the depression of the transition temperature was not a direct function of the skin effect. It would appear, then, to be a function of the frequency of the current in the metal alone.

Experiments with Simultaneous Direct and Alternating Currents

Some interesting results have been obtained by passing direct and alternating currents simultaneously through supra-conductors.

In one of these experiments a tantalum conductor in the form of a solid wire was used. The graph given in Fig. 2 shows the results obtained. The magnitude measured was the direct current resistance, and the curves show that the presence of the high-frequency currents delayed the initial appearance of the approach to the supra-conducting state and enhanced the direct current resistance in the transition stages. The temperature at which supra-conductivity was complete according to the D.C. measurements was not, however, affected by the presence of the high-frequency current in the wire. This was due, of course, to 'skin effect', for the disturbing action of the high-

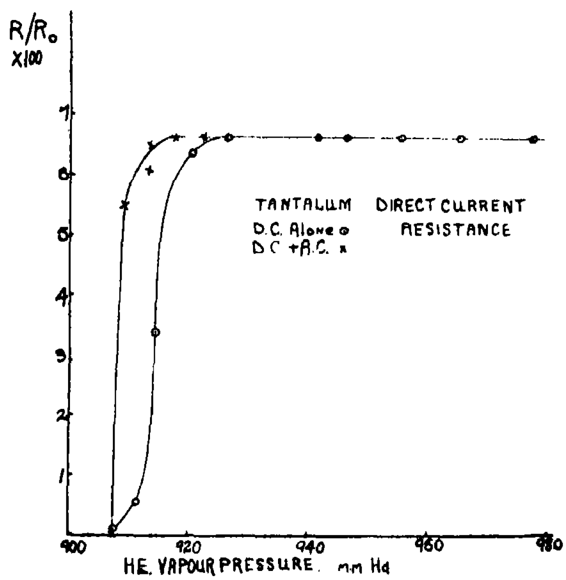

FIG. 2.

frequency currents when the wire was at a sufficiently low temperature to be supra-conducting for D.C. measurements was confined entirely to the outer layers of the wire.

In another experiment which was rather instructive, a conductor was constructed by 'wiping' a layer of block tin upon a *constantan* wire, of diameter 0·016 cm. The tin skin was of average thickness about 1/500 mm., and its presence decreased the resistance of the wire at room temperature by about seven per cent. Calculation shows that at the low temperatures just above the supra-conducting point the resistance of the constantan was then about thirty times that of the tin.

The results of measurements made with this wire are shown by the graphs of Fig. 3, which represent the relation between the direct current

resistance ratio R/R_0 and the temperature, both without high-frequency currents present, and with the high-frequency and direct currents flowing simultaneously in the metal.

It can be seen that when, in addition to the direct current, high-frequency currents were passed through the wire, the resistance was changed so that the curve AB first obtained was shifted to lower temperatures, becoming the curve $A'B'$. The switching on and off of the high-frequency generator changed the resistance reversibly from

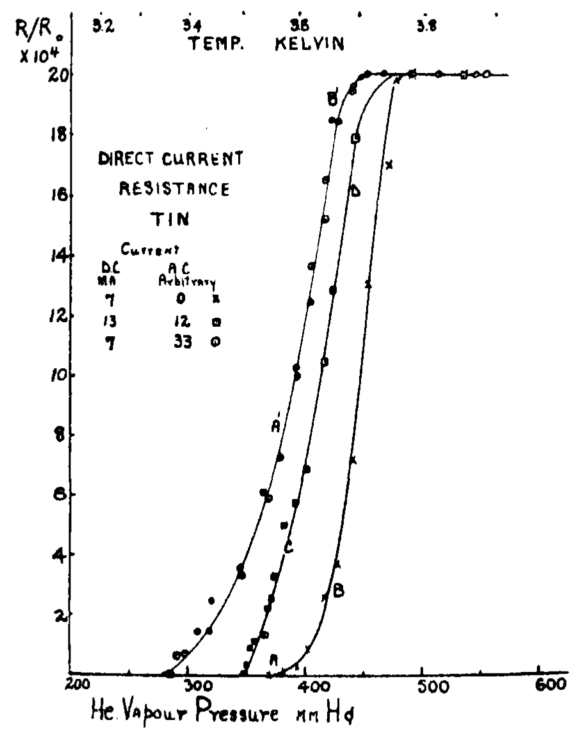

FIG. 3.

the point A to A', B to B' and so on. The magnitudes of the shifts A to A' and B to B' increased, as the curves show, with an increase in the ratio of the strength of the high-frequency current to that of the D.C. one. Even when the resistance had become zero on the undisturbed curve it could be partially restored to the tin layer by switching on the alternating current. Moreover, the curves clearly show that the presence of alternating high-frequency currents in the tin coating on the wire had the effect of lowering the temperature at which with D.C. measurements the tin layer became supra-conducting.

It may be of interest to state that when observations were made with this tin-coated wire on the resistance it offered to high-frequency currents, it was found that the addition to it of a direct current had the effect of removing partially or wholly the high-frequency resistance. The graphs in Fig. 4 illustrate this point.

The results of the experiments with high-frequency alternating currents would seem to justify the conclusion that a polarisation or orientation phenomenon of some kind must be involved in the production of the supra-conducting state in metals.

In the discussion, Prof. W. J. de Haas expressed the view that it seemed probable that the electrons go over into a new phase when the metals become supra-conductive, and in order to support this view certain experiments had been carried out by him and his associates on the conductivity of single crystals. Formerly the region of disappearance of resistance was about 0·03°, but he had found that for good single crystals and small measuring currents this region did not exceed 0·0005°. He and his associates had investigated the influence of the crystal lattice on grey and white tin, which differ only in this respect that grey tin does not show supra-conductivity, while white tin does. Gold-bismuth alloys show the same influence—the alloy becomes supra-conductive though neither of the components do. X-ray experiments, however, showed that this alloy has a crystal lattice of its own.

Investigations of the thermal conductivity of supra-conductors shows an influence of the supra-conductive state. At the transition point, indium shows a small sudden increase of thermal conductivity. When the supra-conductivity is disturbed by a magnetic field, the thermal conductivity is increased for pure metals. The results for $PbTl_2$ are very complicated, probably as a result of the lack of homogeneity of the alloy. The specific heat of tin increases when the metal becomes supra-conductive. In a magnetic field high enough to disturb supra-conductivity, this increase disappears.

Prof. O. W. Richardson pointed out that there is some resemblance, even though it may be only superficial or accidental, between supra-conductivity and ferromagnetism. Following this idea, Keesom and his associates at Leyden have measured the specific heat of supra-conductors in the neighbourhood of the critical point, where one might expect an abnormality similar to the abnormality in the specific heats of ferromagnetic substances in the neighbourhood of the Curie point; but no such effect could be detected. This, however, is not entirely conclusive. The

number of electrons concerned in the supra-conductive phenomenon may be too small a fraction of the total number, or of the number of atoms present, to exert any appreciable influence on the specific heat, or, alternatively, there may be some compensating effect on the atoms which may counterbalance any changes in the specific heat of the whole substance arising from changes in the energy of the electrons.

Dorfman has pointed out that a test which is in some respects a more direct one of this particular issue can be made if the specific heat of electricity (Thomson effect) in the supra-conductive region of temperature is considered. The magnitude of this effect can be deduced from the thermoelectric measurements of Keesom and his associates which refer to lead and tin. These show that there is such an abnormality in the Thomson effect. It is true that it does not occur exactly at the supra-conductive critical temperature. For example, in the case of lead this critical temperature is 7·2° K.; whereas the anomaly in the Thomson effect sets in at about 5° K. and rises to a maximum at a little above 10° K., after which it falls. This anomaly is quite similar to the corresponding anomaly in the case of ferromagnetic substances near the Curie point.

If it is admitted that this anomaly in the Thomson effect is associated with the establishment of supra-conductivity, it is a natural inference that it is a result of the change in the energy of an electron connected with this phenomenon. On this basis, the thermoelectric data enable the difference ΔW_0 between the energy of a supra-conducting and a non-supra-conducting electron to be estimated. The interesting fact then emerges that, approximately,

$$\Delta W_0 = \mu H_0 = h\nu_0$$

where μ is the spin moment of the electron, H_0 the magnetic field necessary to destroy the supra-conductivity, h is Planck's constant, and ν_0 McLennan's destructive frequency; ΔW_0, H_0 and ν_0 are all extrapolated to the absolute zero of temperature. In other words, the magnetic energy and the vibrational energy required to break up the supra-conductive structure are each approximately equal to the energy of the structure itself.

Dr. W. Meissner described experiments in which very slow-moving electrons are made to impinge upon a sheet of tin-foil at temperatures both above and below the transition temperature of tin, 3·7° K. His object was to see whether the foil when supra-conductive is transparent to such slow-moving electrons. It was found not to be so, although by his experimental arrangements the velocities of the impinging electrons after their entrance into the tin-foil were probably not greater than the velocities with which the conducting electrons in the metal, according to recent theories, are supposed to be endowed.

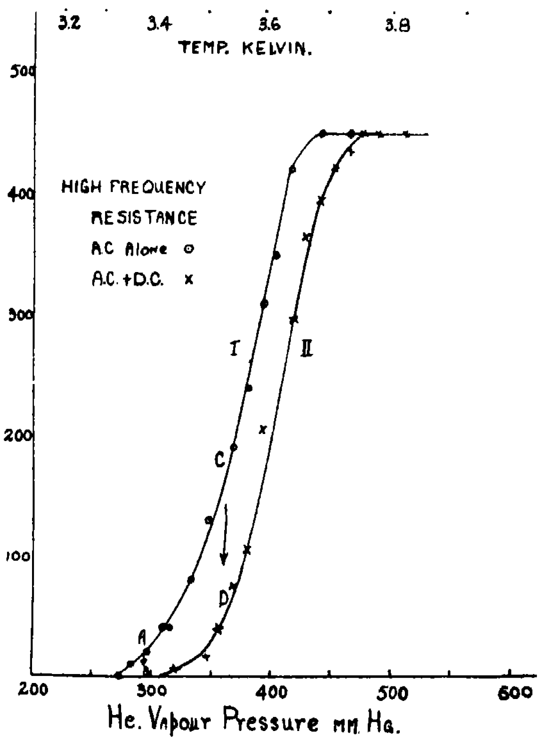

FIG. 4.

Electron Lattice Theory

Interest in the problem of supra-conduction in metals has been stimulated recently by a view put forward independently by Prof. Niels Bohr, of Copenhagen, and by Prof. R. de L. Kronig, of Groningen, in communications to McLennan. The essential feature of this view is that the conducting electrons in a metal are supposed to form a crystal lattice of their own in addition to that formed by the atom-ions of the metal.

According to quantum mechanics, it appears that this electron lattice can move through the wire lattice without dissipation of energy even when the wire lattice is in thermal agitation. In other words, the metal will be supra-conducting whenever the electron lattice exists.

On this view of supra-conductivity, the transition point or temperature at which the metal passes from the supra-conductive state to the ordinary conducting one may be interpreted as the melting point of the electron lattice. The view that the conducting electrons in metals may build a lattice has already been put forward by Prof. F. A. Lindemann[7] and the suggestion was made both by him and by Sir J. J. Thomson that this idea may provide a basis for an explanation of the phenomenon of supra-conduction in metals. Without the aid of quantum mechanics, however, it was not clear that an electron lattice of the type now invoked could be stable and could be given a translatory motion without dissipation of energy through the wire lattice of a metal endowed with thermal agitation.

The electron lattice theory is a promising one, for it affords a direct and ready explanation of a number of the phenomena associated with supra-conduction in metals. The final verification of the theory will probably be reached through a study of the conductivity of single crystals of metals at the lowest temperatures. As de Haas has indicated, investigations have been begun already in this direction.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD., ST. ALBANS

work on the taxonomy of Hymenomycetes. Mycological classification is emerging from a state of chaos, and the student or amateur will be able to orientate much knowledge which formerly puzzled him. The address is published in the *Transactions* of the Society (vol. 17, pp. 16–34, 1932) and will serve as a valuable guide to the most important literature on the subject.

Physical Society's Exhibition

THE twenty-third annual exhibition of scientific instruments and apparatus, arranged by the Physical Society, will be held on January 3–5 at the Imperial College of Science and Technology, South Kensington, S.W.7. It will be open in the afternoons from 3 P.M. until 6 P.M. and again in the evenings from 7 P.M. until 10 P.M. The leading manufacturers of scientific instruments will be exhibiting their latest products in the Trade Section. The Research and Experimental Section will contain contributions from most of the important research laboratories in Great Britain, and there will be a special sub-section devoted to experiments of educational interest. In addition, the work submitted for the craftsmanship competition by apprentices and learners will be on view. Discourses will be delivered each day at 8 P.M. as follows: January 3, Dr. Allan Ferguson: "Surface Tension and its Measurement"; January 4, Mr. R. A. Watson Watt: "Cathode Ray Oscillography"; January 5, Mr. F. Hope-Jones: "Time Measurement: Old and New". Members of institutions and scientific societies may obtain tickets from their secretaries; tickets may also be obtained from the Exhibition Secretary, 1, Lowther Gardens, Exhibition Road, S.W.7. Admission on January 5 will be free, without ticket.

Announcements

THE Buchan prize of the Royal Meteorological Society for 1933 has been awarded to Mr. David Brunt, for papers contributed to the *Quarterly Journal* and *Memoirs* of the Society during the years 1927–31.

PROF. G. ELLIOT SMITH, professor of anatomy in University College, London, has been appointed Fullerian professor of physiology at the Royal Institution to succeed Prof. J. B. S. Haldane, whose tenure of office expires next January.

THE Lawrence research studentship of the Royal Society has been awarded to Miss P. A. Clapham, who proposes to work at the London School of Hygiene and Tropical Medicine on helminthic infestation and nutritional deficiency.

A DISCUSSION on "The Chemistry of the Sterols and Bile Acids", to be opened by Prof. I. M. Heilbron, H. Harrison professor of organic chemistry in the University of Liverpool, will be held at the Chemical Society on Thursday, December 15, at 8 P.M.

DR. ULICK R. EVANS has been elected to the research fellowship in metallurgy of the Armourers and Brasiers' Company, in succession to Dr. W. Hume-Rothery. The award is made by a joint committee of the Royal Society and the Armourers and Brasiers' Company.

MR. COLIN HARDIE, fellow and classical tutor of Balliol College, Oxford, has been appointed to succeed Mr. Arthur Hamilton Smith as director of the British School at Rome as from January 31, 1933.

SIR HENRY DALE, director of the National Institute for Medical Research, will deliver the Harrison memorial lecture of the Pharmaceutical Society of Great Britain on December 13. The title of Sir Henry's lecture will be "Therapeutic Problems of the Future". At the conclusion of the lecture, the Harrison Medal will be presented to Sir Henry Dale.

To commemorate the bicentenary of the birth of Sir Richard Arkwright, inventor of the yarn spinning frame, the Newcomen Society has arranged for a public lecture to be delivered on December 14, at 5.30. The lecture will be given at the Science Museum, South Kensington, London, S.W.7, by Mr. Frank Nasmith.

MR. A. ABBOTT, formerly chief inspector for technical education at the Board of Education, has been awarded the Institute Medal of the Textile Institute. Mr. Abbott was formerly assistant secretary to the Department of Scientific and Industrial Research and did much work in connexion with the establishment of the Cotton Research Association.

THE twentieth annual meeting of the Indian Science Congress will be held at Patna on January 2–7 under the presidency of Dr. L. L. Fermor, director of the Geological Survey of India. The Congress will meet in nine sections, namely, agriculture, mathematics and physics, chemistry, zoology, botany, geology, medical and veterinary research, anthropology and psychology. The local secretaries are Dr. K. S. Caldwell and Prof. Kamta Prashad, both of the Science College, Patna.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant teacher of engineering science, handicraft and drawing at the Radcliffe Technical College—The Secretary of Education, Town Hall, Radcliffe, near Manchester (Dec. 14). An executive engineer and an assistant engineer (mechanical) to the Government of Madras for harbour works at Cochin—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Dec. 23). A public analyst to the City of St. Albans—The Town Clerk, Municipal Offices, St. Albans (Dec. 31). A principal at the Handsworth Technical College—The Chief Education Officer, Education Office, Margaret Street, Birmingham (Dec. 31). A University reader in psychology at Bedford College, London—The Academic Registrar, University of London, S.W.7 (Jan. 26). A University reader in physiology at Guy's Hospital Medical School—The Academic Registrar, University of London, S.W.7 (Feb. 17).

Hexuronic Acid as the Antiscorbutic Factor

A CHARACTERISTIC property of Prof. Szent-Györgyi's hexuronic acid is its behaviour towards iodine. Two atoms of iodine are taken up in aqueous solution (neutral or acid) with formation of two molecules of hydrogen iodide. We find that this is due to oxidation at a double bond. The intervention of water is essential and the product, which is not a di-iodide, can be reduced to hexuronic acid. Regeneration of hexuronic acid occurs only when the aqueous solution of the oxidation product is reduced, for example, by evaporation in the presence of hydrogen iodide.

The biological activity of the acid is probably due to this double function of oxidation and reduction which, unique among purely carbon compounds, is reminiscent of the behaviour of glutathione. The product obtained by the action of neutral iodine on the acid undergoes further oxidation by sodium hypoiodite. One atomic proportion of oxygen is absorbed, two new carboxylic acid groups are formed and oxalic acid (1 mol.) is produced quantitatively. Acid permanganate introduces one atom of oxygen into hexuronic acid with extreme readiness and thereafter oxidation proceeds more slowly with elimination of carbon dioxide until three atoms of oxygen have been absorbed. This leads to the formation of a trihydroxy butyric acid (possibly *d*-threonic) which has been isolated as the optically active crystalline amide $CH_2OMe.CHOMe.CHOMe.CONH_2$. When heated with hydrochloric acid hexuronic acid gives furfural in quantitative yield. These observations suggest that hexuronic acid (which, from analysis of its salts we have proved to be a monobasic acid $C_5H_7O_4.COOH$ and not a lactone of an acid $C_5H_9O_5.COOH$) has the structure $COOH.CO.CO.CH_2.CHOH.CH_2OH$.

The following observations which we have made are consistent with this view. Hexuronic acid forms a di-phenyl-hydrazone $C_6H_8O_4(:N.NHPh)_2$, also a hydrated di-(*p*-bromo-phenylhydrazone), and reacts slowly at 15° with *o*-toluylene diamine giving a well-defined condensation product. The sodium or calcium salt of hexuronic acid gives an intense violet colour with ferric chloride but with the free acid the coloration is fleeting. The sodium salt gives with sodium nitroprusside a deep blue colour, changing to green and then red. The acid and its salts show an intense absorption band with head at about 265 mμ.

Hexuronic acid contains one carboxyl and three potential hydroxyl groups (alcoholic or enolic) and gives a triacetate and a trimethyl ether which both reduce neutral permanganate. When heated at about 175° the acid loses carbon dioxide without darkening or melting (when heated rapidly the pure acid melts at 192°). Whilst the acid has $[\alpha]_{5780}$ + 24° in water the sodium salt has a much higher rotation, +105° in neutral solution, +135° in *N*/10 alkali, (keto-enol transformation). Hexuronic acid appears to be incapable of forming a lactone and its solutions do not display mutarotation. The slow change ($[\alpha]_{5780}$ + 24° → 31°) which occurs with aqueous solutions in glass vessels is due to partial neutralisation of the acid by alkali dissolved from the glass. Alkaline solutions of the acid are stable in the absence of oxygen.

These observations indicate the presence of an optically active diketo-acid containing a $-CH_2-$ group. These groups must be united in such a way that the stringent requirements of the crystallographic and X-ray data are satisfied. It is essential, for example, that the carbon and oxygen atoms (with one exception) should lie in a plane and that the length and breadth of the molecule should be 8·8 and 6·1 A. respectively. A critical survey of various possibilities from the chemical, optical and X-ray data has led us to the conclusion that the properties of hexuronic acid are best accounted for by the above structure. This can react also in the enolic modification, $CO_2H.CO.C(OH)=CH.CHOH.CH_2OH$.

We have examined (with R. W. Herbert) the absorption spectrum of de-citrated lemon juice and have estimated that the hexuronic acid content corresponds with the recorded evaluation of the antiscorbutic activity of isolated hexuronic acid.

A Peculiar Visual Experience

WHILE I was engaged in flashlight colour photography, using large charges of magnesium and the ordinary touch-paper method of ignition, the fuse on one occasion apparently failed to act, but, just as I was about to replace it, the flash took place. My head was less than a foot above the explosion point, and the flame must have reached my face, as my eyebrows and hair were singed, and my spectacles were completely coated with a dense, firmly adherent film of magnesium oxide.

My subsequent visual sensations were as follows: for an indeterminate period, which, after making generous allowance for subjective impressions, I would estimate at about twenty seconds, there was a complete 'black-out'. After this period (during which I removed my glasses and rubbed my eyes) I observed the filament of a 100 watt gas-filled lamp, about three feet distant and screened by a thin orange silk shade, which appeared as a bright red line. In about twenty seconds more (this and subsequent times were taken with a watch) I could distinguish general details of the furniture of the room, which was fairly well lighted, in red monochrome. The colour changed from deep maroon to light claret in about fifteen seconds, and then to an orange shade in about ten seconds more, but a prominent red object retained its normal shade. Then the background and white objects changed suddenly—too quickly for the time to be observed—to a green, at first olive, afterwards brightening to emerald. This stage lasted nearly twenty seconds, and it was noted that the red and orange objects appeared in their natural colours. The green shade then faded away rapidly, and the whites, after a slight intermediate yellow tinge, appeared for the first time. The total illumination appeared to

increase steadily over the whole period of about ninety seconds; examination of the pupils showed that they were still abnormally contracted at least two minutes after the flash took place. Owing to nervous reaction, I am unable to state whether further after-images or colour changes occurred.

I presume that the flash had reached its maximum intensity before the pupil or eyelid reflex could operate, and that the eye was exposed to a very powerful beam of strongly actinic light. The peculiarity was that colour sensation was regained discontinuously, and not in the spectral order that might have been expected. The failure to observe any blue phase in the after images, as described by Washburn[1] and McDougall[2] in their experiments where the eye was exposed to white light of moderate intensity, is readily explicable; but the change in the red shade and the sharp succession of the green, followed by the yellow, is much more difficult to comprehend. I should be interested to know if it can be satisfactorily explained on the existing theories of colour vision, and whether other experiences of similar causation and result have been observed.

Records of Pelagic Animals in Scottish Waters

IN their interesting letter to NATURE (Oct. 29), Dr. Stanley Kemp and Dr. F. S. Russell refer to the abnormal distribution of certain pelagic animals during the current year as pointing to unusual hydrographic conditions. In Scottish waters also, conditions seem to have been somewhat disturbed, judging by the occurrence of certain other animals.

Whales and dolphins appear to have been specially plentiful if the record of stranded specimens bears any relation to the actual numbers present in the adjacent sea. Already this year ten specimens have been reported,[1] while in 1931, 1930 and 1929 the numbers were four, none, and three respectively. The most interesting was a young white whale, *Delphinapterus leucas*, a rare arctic visitor, taken in the Firth of Forth.

Early in November, also, a long-finned tunny (*Thynnus germo*) was taken at Lochgoilhead in the Firth of Clyde. (Full details will appear in the next number of the *Scottish Naturalist*.) Apparently, this is only the second record of this southern species in Scottish waters.

Fixation of Mitochondria

IT has been known for many years that Carnoy, Gilson, Petrunkevitch, corrosive acetic, Bouin, and a host of ordinary fixatives will enable remains of mitochondria to be demonstrated with staining in alum hæmatoxylin or acid fuschsin. This applies especially to cytoplasmic inclusions when aggregated as in the spermatogonium, or in the mitochondrial *nebenkerne*. Mitochondria often show nicely after acetic acid containing fixatives such as the 'Susa' mixture or Flemming with acetic acid. This applies especially to all vertebrate tissues. With most invertebrate tissues such methods are deadly, and if mitochondria remain they are almost certainly badly distorted. Practically all the beautiful work of Meves was done with acetic acid containing fixatives. This is why he left so much to be done by those who followed.

Bouin's fluid contains formalin, which often enables surprisingly good results to be obtained with this fixative, and in the case of bulky insect or other testes, the concentration of acetic acid in this fixative becomes lessened as the innermost parts of the tissue are reached. In any event, the objection to acetic acid is that if it does not dissolve much of the cytoplasmic bodies, it distorts them badly ("Vademecum" § 697). Scorpion spermatocyte mitochondria are completely wrecked by Flemming with acetic and only occasionally properly 'set up' for passage through the alcohols and xylol, by using Flemming without acetic. Post-chroming for such objects is very necessary ("Vademecum" § 710). In some cases for staining, the post-chroming may be delayed until the sections are actually in the slide. This was done in the case of Duesberg's beautiful paper on the relationship between the organ-forming substances and the cytoplasmic inclusions in the ascidian egg. It might be possible, as Dr. John Baker has suggested[1], to develop the technique of post-chroming Bouin (without acetic) material so as to get material up to a research standard ("Vademecum" § 710). The advantage of this is that formalin and picric acid are cheap and easily transported, whereas the osmic and silver methods are tricky. Some years ago, I got a number of *Lepidosiren* sent over from the Chaco in a tin of Bouin without acetic. The fixation was splendid but there was no spermatogenesis in progress. The fluid had eaten the tin only slightly, and the discoloration of the Bouin, when the tin was opened, did not appear to have damaged the fishes. In the case of these *Lepidosiren*, post-chroming did not improve the staining of the mitochondria, nor did it bring out the Golgi bodies. For these the proper methods are the only satisfactory ones.

Hybridism in Eels

IN New Zealand there are two species of eel recognised by J. Schmidt.[1] These are the short-finned eel, *Anguilla australis*, and the long-finned eel, *Anguilla aucklandii*. Latterly I have shown that *Anguilla aucklandii* must become *Anguilla dieffenbachii* on the grounds of priority.[2] Sexes of eels keep apart in our fresh water and in the migration seawards of eels in the autumn this segregation of the species is usually most marked. The male in both species is small, while females are much larger, the last to migrate seawards being the large female *A. dieffenbachii*, which generally measure more than 5 ft.

Schmidt has noted that in *australis* the vomerine band of teeth is pear-shaped, and in *dieffenbachii* this band tapers well back on the roof of the mouth as far as the maxillary band. Another feature noted also by Schmidt is the fact that the angle of the mouth in *dieffenbachii* extends back beyond the eye whereas in *australis* this angle is stated to be approximately below the hind margin of the eye. Larval *dieffenbachii* sent to me some years ago from Mataura

Falls, Otago, have the angle of the mouth reaching only to under the centre of the eye. As this is the large-mouthed species of eel, it is possible that we have here a hybrid with the mouth of *australis* and the fins of *dieffenbachii*.

In April 1932, I had the opportunity of visiting Lake Ferry, Wellington, through which many eels run in the seaward migration. Among a number of male long-finned eels, I found a female of the short-finned species which was caught with them. This example is 35·7 in. long, and has the fins and small mouth as in *A. australis*; but the teeth are as in *A. dieffenbachii*. The vomerine band is widest about the centre and tapers well backwards reaching nearly as far back as the maxillary bands. While this tapering band of teeth does not reach quite so far back as it should to be exactly true to *dieffenbachii*, it is certainly not pear-shaped and is close enough to that species in this important respect. I can only conclude that the eel which I have mentioned is a hybrid between our two common species, thus shedding new light on the species problem of *Anguilla* throughout the world.

Priapulus caudatus in New Zealand Waters

THE antarctic variety of this northern species of *Priapulus*, whether it be called *tubercule-spinatus* Baird or *antarcticus* Michaelsen, is confined, according to recent authorities, to the most southern seas; for example, off Tierra del Fuego, Patagonia, South Georgia, Falkland Is., Graham area, Cape Adare, Kerguelen.

Early in this year I received from Mr. A. B. W. Powell, the conchologist at the Auckland Museum, a collection of polychætes dredged in the harbour at that city, and in one of the phials I found to my intense surprise a small specimen of *Priapulus* measuring about one inch in length. It is well preserved and exhibits the characteristic arrangement of the spines or teeth described by Theel and so beautifully figured by his artist. It was obtained at a depth of 8 fathoms in Islington Bay, Auckland Harbour, associated with *Terebellides stroemi*, *Lanice conchilega*, and *Lagis australis*; the bottom was of black gritty mud.

As the variety has never been recorded from so far north it seems worthy of record in NATURE.

University Museum, Dunedin, N.Z. WM. B. BENHAM.

Chemical Composition of the Animal Body

IT is customary to express the results of an ultimate analysis as mass percentages, thus: oxygen, 65 per cent; carbon, 18·25 per cent; hydrogen, 10 per cent, and so on. But, on modern views, the chemical activities of these elements do not depend on the nuclear masses of the atoms but on their outer valency electrons. Therefore the chemical composition of, say, clupein (the protamine of the testis of the herring) is best expressed as $C_{30}H_{57}N_{17}O_{6}$, or by some such empirical formula. When the results are stated in this way it appears that the order of abundance of the chemical elements in an animal body *is directly proportional to their atomic numbers, so that the characteristic organic element is hydrogen*.

Some interesting speculations are suggested whenever one studies a recent statement of the Periodic Law with this relation in mind. Unfortunately there is no really good complete ultimate chemical analysis of the whole body of any one animal in the literature of physiology, and so it is impossible to be sure as to the order of abundance of oxygen and nitrogen, and of the elements sodium, potassium, etc., in the results. The empirical formulæ of most of the substances composing the tissues are known but it is difficult to 'weight' these numbers according to the proportions of the tissues in the whole body. Perhaps, also, the water in the tissues is really an organic constituent in the same sense as carbon is such a constituent. Is the order of abundance of the mass numbers of the isotopes of oxygen and nitrogen known in cases where these elements have been isolated from living organisms? Other questions immediately occur to one and it is plain that here there is something to be investigated.

Magnetic Rotatory Dispersion and Absorption of the Cerous Ion in Solution

BECQUEREL and de Haas,[1] from their work on the magnetic rotation of the crystal tysonite, predicted that the Ce^{+++} ion possesses an intense paramagnetically active absorption band in the neighbourhood of λ 2370 A. This prediction was based on the assumptions that (1), although tysonite is a complex fluoride of Ce^{+++}, Pr^{+++} and Nd^{+++}, the only sensibly rotating ion is Ce^{+++}; (2) the rotation due to Ce^{+++} is controlled by a single absorption frequency. It occurred to us that it would be of interest to test the validity of this predicted property of the Ce^{+++} ion, by investigating the magnetic rotation of solutions of cerous salts in the visible and near ultra-violet regions of the spectrum.

By means of the polarimetric method of Bruhat and Pauthenier[2] (without using double monochromator) we have investigated at room temperature the magnetic rotation of three solutions of cerous sulphate in water, of strengths approximately 0·7, 2·7 and 4·4 per cent, for the mercury lines 5780, 5461, 4358, 4046, 3652, 3341 and 3128A. Our results for the dispersion of the specific magnetic rotation of cerous sulphate indicate the existence of two paramagnetically active absorption bands; a weak one in the neighbourhood of 300 mμ and a strong one in the neighbourhood of 240mμ. Our results are not sufficiently precise to determine with accuracy the wave-lengths of both these active bands; recourse must be made to absorption data.

Recently, the absorption of the Ce^{+++} ion in solution has been investigated by Bose and Datta,[3] who find in solutions of cerium trichloride in water a weak band at 2960A. and a strong band at 2550A. If we assume in our calculations the wave-length of the weak active band to be 296mμ, we find the value 239mμ for the effective wave-length of the strong band. It must be pointed out that this absorption band alone, although having a wave-length in close agreement with that obtained by Becquerel and de Haas, will not account for the ultra-violet dispersion of cerous sulphate as determined by us.

In comparison with the value 255mμ given by Bose and Datta for the position of the strong absorption band, the value 239mμ seems to indicate the presence of other absorption bands of the Ce^{+++} ion

having shorter wave-lengths than 255mμ. At our request, Dr. R. A. Morton kindly investigated the absorption spectrum of a solution of cerous sulphate in water. In addition to bands occurring at 296mμ and 254mμ, he found strong bands at 240mμ and 223mμ. As our value 239mμ is to be regarded only as an effective wave-length, and as, according to the absorption measurements, the intensities of the bands 254mμ, 240mμ and 223mμ are of the same order of magnitude, it would appear probable that all these bands are active. It must be mentioned that absorption bands with roughly these wave-lengths have already been found by Freed[4] in a mixed crystal of lanthanum and cerium ethyl sulphate.

In our calculations, we have neglected the dispersion due to the sulphate ion. As the characteristic frequency of this ion is very high compared with the frequencies considered, we should expect the contribution of this ion to the magnetic rotation to be very small. By means of further experiments we hope to be able to estimate the effect due to the sulphate ion.

Gyromagnetic Effect in Some Ferromagnetic Powders

BOTH the gyromagnetic effects, namely, the production of (1) magnetisation by rotation, and of (2) rotation by magnetisation, have been applied to deduce the ratio of angular momentum to magnetic moment of the elementary magnet in ferromagnetics. The theoretical value of this ratio R for an orbital electron is $2m/e$ and for a spinning electron m/e. Results of observations on all ferromagnetics by the method of rotation by magnetisation gave values[1] of R exactly equal to m/e within very narrow limits of experimental error, which is less than one per cent for the metallic rods, and about five per cent for the powders investigated. Making use of the first effect, Barnett[2] found for the ferromagnetic metals values of R which, according to his estimate, are several per cent higher than the orthodox value for the spinning electron. This may mean that the orbital moment is also partly effective in producing ferromagnetism.

At the suggestion of Prof. D. M. Bose, I undertook in his laboratory the gyromagnetic study of a number of substances, among them some ferromagnetic powders. The method employed was the resonance method of Einstein and de Haas, and the apparatus was very similar to that used by Sucksmith.[3] The material was packed in a thin glass tube of length about 6 cm. and of diameter varying from 1·3 mm. to 2·3 mm.; the field applied was about 230 gauss and the vacuum method was employed to get increased resonance amplitude, which for the thinner tubes was about 3 cm. at a scale distance of 130 cm. The following results have been obtained:

	R
Fe_3O_4 (precipitated)	1·008 m/e
Fe_2O_3 (ferromagnetic)	1·016 m/e
NiO, Fe_2O_3	1·022 m/e

The error in all probability does not exceed two per cent, so that for these substances, as for the others investigated by the same method (that is, rotation by magnetisation), the value of R realised is the exact value for the spinning electron.

Anthropology of Veddahs

IT may interest many readers of NATURE to hear of the results of my recent expedition into the Veddah territory in the interior of this island. The expedition took place on September 18–25 of this year. The part visited was the Nilgala division of the Uva Province, where probably the best Veddahs in Ceylon still live. The track lay through the Sinhalese villages of Hamapola, Pitakumbura and Bulupitiya. In some of these the inhabitants betrayed very obvious traces of Veddah admixture. From the last-named place the track led on to the Veddah settlement of Dhanigala. Practically all the Veddahs of this area were collected together and photographed, whilst all the males were measured anthropometrically. The one-time chief of this group, Tuta, whose photograph is given in Seligmann's "The Veddas" had died some time previously. His grave was pointed out to me and I personally removed the skeleton. It was not in a very good state of preservation, but the skull, at any rate, was removed without appreciable damage to the very fragile facial portion.

After spending a night here the expedition was carried on over a range of hills to another Veddah settlement at Henebedda. The living Veddahs were examined and measured as before, and in addition I was fortunate in securing two very complete skeletons. One, a male, belonged to Poromala, probably the one pictured in Seligmann's book. This was comparatively recent, and in perfect preservation. The other was that of a young female named Handhi, who, judging from her skeleton, had suffered severely from yaws. This had caused some atrophy of the bones of the left upper limb, and had left large spindle-shaped swellings on both tibiæ. Apart from these points the skeleton is in very good preservation, and compares favourably with the others.

All the skeletons agree in certain important points that are probably characteristic of the race. In the two males the tibiæ are markedly platycnemic. The pathological condition in the female skeleton precludes a judgment on this point. In only one humerus (in the old man, Tuta) was there a perforated olecranon fossa. This is contrary to the Sarasins' statement that it was common in Veddahs. As a matter of fact, one finds the condition in almost every Sinhalese and in many Tamil humeri, so that it is of little diagnostic importance. All the skulls agree well in general character with one another and with certain others labelled as Veddahs which have been loaned to me by the Colombo Museum through the kindness of the Director. It is interesting to note that two of these three skeletons present each an unusual anomaly. The female skeleton has a marked sacralisation of the last lumbar vertebra, associated with complete absence of the last pair of ribs. The skeleton of Poromala presents a complete degree of non-union of the neural arches in the sacral vertebræ.

It is proposed to publish a preliminary report on the three skeletons in the *Ceylon Journal of Science*. Detailed consideration will be left until a more complete study has been made, and opportunity for comparison with other reputed Veddah material in the various museums in Europe has been taken. It is also hoped that further new material will shortly be forthcoming from the Bintenne and Tammankaduwa districts of the Veddah country.

I may add that a complete collection of hair from various parts of the body in both sexes and at several ages was taken from the Dhanigala Veddahs. This will be studied and compared with the hairs of other Ceylon races. Further hairs were obtained from graves of Poromala and Handhi. I should be delighted to exchange samples of this for hair of other races with any anthropologist in possession of such material.

Dimensions of Fundamental Units

PROF. W. CRAMP has suggested[1] that the quantities Q, L and T have better claim to be regarded as fundamental than M, L and T. His argument is based on the assumption that Q shall be a function of M. Such an assumption would be a bombshell in modern physics. M, in common with L and T, is a quantity which varies with the velocity of the observer; Q does not so vary.

The wiping out of all fractional indices from the dimensional expressions for the electrical quantities, current, flux, E.M.F., etc., by leaving Q in those expressions is scarcely noteworthy. Fractional indices come into the dimensional expressions for electrical quantities at the outset when, by writing $(Q \times Q/kL) = F = MLT^{-2}$ we find $Q = k^{\frac{1}{2}}M^{\frac{1}{2}}LT^{-1}$. If Q were left in, no fractional indices would appear and also no k; and since, if we neglect both k and μ the ratio of the electromagnetic units to the electrostatic units is always a velocity, or a velocity squared, or the reciprocal of one of these—that is to say, contains no fractional indices—it follows that the presence of Q wipes out fractional indices from dimensional expressions in both the electromagnetic and the electrostatic systems.

University of New Mexico,
Albuquerque.
Oct. 19.

[1] NATURE, 130, 368, Sept. 3, 1932.

MY old student, Prof. F. M. Denton, has, I know, given a good deal of attention to the theory of relativity, and this no doubt has led him to question the possibility of any dimensional relationship between M and Q. While not pretending to have the same knowledge of Einstein's theory, it does seem to me that there is little experimental evidence for the assumption that M varies with the velocity of the observer while Q does not. It would be interesting to know upon what grounds Prof. Denton makes so positive a statement.

Recalculation of Mass Defects

THE well-known mass defect curve of the old nuclear scheme calculated with regard to α-particles and protons presented a difficulty with its minimum of binding energy for tin and an increasing portion between tin and lead. On the other hand, the mass defect values against protons give a rather smoothly decreasing curve.[1] As has already been pointed out,[2] the number of α-particles must be considerably reduced from the point of view of the new scheme, which does not admit any electrons in nuclei, but only neutrons and protons (presumably joined as α-particles). The curve of mass defect against protons and neutrons (perhaps with a single 'central' α-particle) is very similar to the old curve against

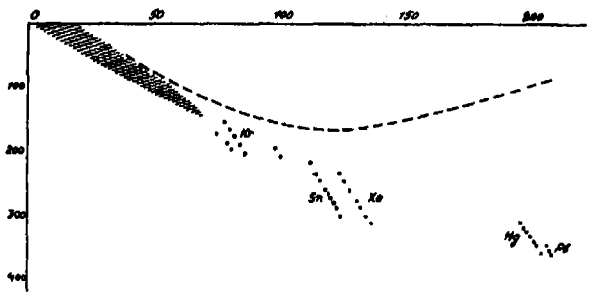

FIG. 1.

protons, but decreases less rapidly. Clearly the new mass defect values relatively to α-particles, neutrons and protons must lie somewhere between the old values computed relative to protons and α-particles respectively (because the number of α-particles is decreased). We may emphasise that this new mass defect curve shows no increasing portion between tin and lead. For illustration we give two typical values:

Old: $50Sn^{124} = 31\alpha + 12\varepsilon$; mass defect $= 0 \cdot 158$ (in mass units);
$82Pb^{208} = 52\alpha + 22\varepsilon$; mass defect $= 0 \cdot 035$.
New: $50Sn^{124} = 25\alpha + 24\omega$ (ω = neutron); mass defect $= 0 \cdot 304$;
$82Pb^{208} = 41\alpha + 44\omega$; mass defect $= 0 \cdot 366$.

On the accompanying graph (Fig. 1) are plotted the new mass defect values; the dotted line shows the old smoothed curve.

The significant result mentioned above depends not on the doubtful decimals in the value of neutronic mass but only on the fact that the number of α-particles is diminished in comparison with the number usually admitted, some being split to neutralise the 'nuclear electrons'.

Process of Space Quantisation

THE following note is a report of researches into the process of space quantisation, carried out during the last two years in the Institute of Physical Chemistry in Hamburg.

The problem may be stated as follows. When a ray of potassium atoms is sent through an inhomogeneous magnetic field, it is split into two rays (space quantisation). If one of the rays is then screened out, all atoms in the remaining ray have the same

axial direction (that is, the same component of magnetic moment in the direction of the field). The ray is then sent through a homogeneous magnetic field, the direction of which is changing with time (for example, a rotating field). After the ray has passed this rotating field, it goes through a second inhomogeneous field. This last field serves to determine whether all the atoms still have the same orientation (in which case they would be deviated towards the same side) or whether some of them have been re-oriented (*umgeklappt*).

The proportion of re-oriented atoms to those having the original orientation depends upon the ratio of the Larmor period, T_l, to the period of rotation of the field, T_f. If T_f is large compared with T_l, that is, if the atom completes many Larmor precessions during the interval required for an appreciable change of field direction—then the process is an adiabatic one and no re-orientation occurs. If an appreciable fraction of the atoms is to be re-oriented, T_f and T_l must be of the same order of magnitude.

Under usual experimental conditions, $T_f >> T_l$; that is to say, the adiabatic case is realised, and no re-oriented atoms are observed. In order that the non-adiabatic case may be realised, the Larmor period T_l must be made as large as possible (that is, very weak fields must be employed), and T_f must be as small as possible. We have succeeded in producing these non-adiabatic conditions in the following manner. The ray passed through a region enclosed in an iron shield where there existed a very weak magnetic field, constant in space and in time. Its strength was a few tenths of a gauss. The variation of the field with time was brought about by causing the ray in its course through the shielded region to pass close to a wire. Atomic ray, wire, and lines of force were at right angles to one another. When a current flowed through the wire, its magnetic field was superposed upon the constant field inside the iron shield. In this way the field was made inhomogeneous in space, and atoms which passed near the wire experienced a change of field direction from point to point; this was equivalent to a variation of the field with time.

We found that with weak currents through the wire (that is, with no appreciable rotation of the field) there were no re-oriented atoms—just as was the case with a strong field (the adiabatic case). But when the constant field was only a few tenths of a gauss, and when the current in the wire was so adjusted that the field of the wire in the region where it was traversed by the ray was also of this order of magnitude, a noticeable part of the atoms (as much as one-third) was re-oriented. The number of re-oriented atoms, and the dependence of this number upon (1) the current in the wire, (2) the distance of the ray from the wire, and (3) the velocity of the atoms, agreed with the theoretical prediction.[1]

Fundamental Frequencies of the Group SiO_4 in Quartz Crystals

THE particular properties of quartz crystals (SiO_2), as compared to those of carbon dioxide (CO_2) have led Sir William Bragg to the conception of considering a quartz crystal as one single molecule.

An analogous constitution is shown by the polymeric homologue series of silica esters, the Raman spectra of which I have recently investigated.[1] It has been observed that in these compounds four characteristic scattered frequencies must be attributed to the group SiO_4. Of these frequencies two are independent of the degree of polymerisation, while the other two show a continuous shift with the degree of polymerisation. The line 642 cm.$^{-1}$ of the monomeric ester which is shifted so far as 518 cm.$^{-1}$ is a conspicuous example of the last mentioned behaviour. The latter corresponds to a line of the decameric ester.

Making use of the above mentioned results, the fundamental frequencies of the SiO_4 group in quartz can be located. The results are seen from the following table.

	ν_1	ν_2	ν_3	ν_4
ν cm.$^{-1}$	502	800	1062-1086	1170-1208
$\lambda\mu$	19·92	12·5	$9{\cdot}4_1$-$9{\cdot}2_1$	8·54-8·28

With the aid of these four fundamental frequencies, the entire ultra-red spectrum of quartz below 10μ can be interpreted as a system of combination bands of the second to the fourth order. Attempts to determine the fundamental frequencies and to arrive at a system of combination bands have been made by Plyler[2] and Parlin.[3] The frequencies assumed by them differ partly from those arrived at above and consequently the values of the frequencies of the combination bands calculated by them agree less well with those observed than in our case.

A more detailed paper will appear in the near future.

Spectrum of Cosmic Radiation

IN the note published by me in NATURE of September 24 under the above title, I find I made a numerical error in the observed limits of the 'soft band'. The observed and calculated values should be:

n	1	2	3	4	5	6
$h\nu$ (calc.)	475	160	80	48	32	23
$h\nu$ (obs.)	~450*	~180	~100	~50	(~30)	~25

Thus, the observed values given under $n = 4$ and $n = 6$ (not 5 and 7 as stated before) are the limits of the 'soft band'. They are estimated approximatively from its penetrating power, measured by Prof. R. A. Millikan[1] in comparison with that of γ-rays of thorium C″, the observed ratio being between 12 and 6.† The value ~ 30 million volts is an average, being at the same time the energy of formation of helium: $h\nu = 0{\cdot}032\ H.c^2$.

With this correction the agreement becomes more complete, the lack of the observed value under $n = 4$, noted in the preceding letter, having disappeared.

ADAM ST. SKĄPSKI.
Institute of Physical Chemistry,
Mining Academy,
Krakow–Poland,
Oct. 17.

* The probable value of the 'iron constituent'.
† The energy of γ-rays of thorium C″ being 2·5 million volts, the ratio 6 corresponds—from the Klein-Nishina formula—to 25 million volts.

Research Items

Animism and Child Psychology.- It is often maintained that the personifications of inanimate objects which are characteristic of the thought of the child in civilisation belong to a stage of mental development corresponding to that which is responsible for the animistic beliefs of peoples of lower culture. Ignoring the refinements of animistic belief, it may be said broadly that the reaction of the civilised child, in speaking of 'the naughty table' against which it has hurt its head, is regarded as comparable with the belief of the savage who holds that some spiritual force or power animates a block of wood or stone, for example, and may act, or be influenced to act, for good or ill. It has, therefore, been only reasonable to conclude that the same attitude of mind would be found, possibly even in an intensified form, in savage childhood; but a recent investigation raises some doubt as to the validity of the whole argument. Miss Margaret Mead has recorded the results of an investigation among the children of the Manus people of Admiralty Islands, New Guinea, with special reference to this point (*J. Roy. Anthrop. Inst.*, 62, pt. 1). Her investigation was conducted both by observation while the children were engaged in free activities, and by question. She found no evidence of animistic personification, although some of her experiments were directly provocative, had there been any tendency in this direction. The drifting of a canoe was attributed not to the innate perversity of the canoe, but to the carelessness of the person who failed to tie it up properly. The evidence, it is true, is drawn from a single people, among whom indeed conditions may be peculiar; but it suggests to Miss Mead, and will suggest to others, the need for a careful reconsideration of this theory of child psychology.

Early Migrations into America.—The evidence collected by a number of expeditions sent out by the Smithsonian Institution in recent years to the far north-west of the American continent has been reviewed by Dr. Aleš Hrdlička in its bearing on the problems of the early migration of man from north-east Asia to America (*Proc. Amer. Phil. Soc.*, 61, No. 6). The expeditions during the last six years have been engaged in systematic work in physical anthropology and archæology over an area extending from Point Barrow to Kodiak Island, and on the principal islands of the Bering Sea. A very large number of sites of ancient habitation have been located, a vast amount of skeletal and cultural material collected and a number of anthropometric observations made on the present inhabitants. Unsuspected rich old cultures have been revealed around the Bering Straits, on St. Lawrence Island, on the lower east coast of the Bering Sea and on Kodiak Island. The work is not yet finished; but it will not be long before the main question at issue shall have been cleared and ascertained fact substituted for the jungle of possibilities which has held the field until recently. The first two points which emerge are negative. Nothing has been found up to the present which indicates a very high antiquity, while it is evident that the Bering Sea region is continuously changing and that one or two thousand years ago the coastal map was quite different from what it is now. Therefore all hope of finding traces of earlier migrants to America must be abandoned. On the positive side, it is evident that once man arrived on the coast of north-east Asia, passing over to the visible coast on the American side was inevitable. Nor is it necessary to postulate a land bridge. Even had it existed man would have used the easier water route. Secondly, the migrations were gradual and disconnected. Thirdly, that man brought with him differences in type, language and culture; and fourthly, that he did not proceed to people America across the mainland, but by skirting the western and eastern coasts of Alaska. The Eskimo, a blood relation of the Indian, was the last comer.

Economic Exploitation of the Birds of Novaya Zemlya.—The transportation of chemical elements through food-chains terminating in the birds of such an area as Novaya Zemlya takes place on a vast scale. The elements of continental soils, transported by rivers, reach the sea, where some are assimilated in the organisms of the plankton. Thence they reach the bodies of fishes and so pass to the bodies of birds to be distributed afresh perhaps in places very far distant from their origin. The possibilities of such transference are suggested by the calculation that the daily catch of marine fishes approximates to a million kilograms, and the weight of fish caught by guillemots during their 120 days sojourn in Novaya Zemlya amounts to about 120,000 tons (L. A. Portenko, *Trav. Lab. biogéochimie Ac. Sci. U.R.S.S.*, Leningrad, 1931, pp. 52). The author describes 36 colonies of birds on the west of the island, and of these the guillemots occupy a coast line of 20 km. Probably they lay about 200,000 eggs, some of which are used by the inhabitants for feeding their blue foxes, while the flesh of the birds is eaten by the people and their dogs. The author also made a special investigation of the eider-down resources of the island, and found that in 1930 the total quantity exported to Gostorg was 457·5 kgm. He is of opinion that the quantities of guillemots' eggs and the production of eider-down offer opportunities for economic exploitation on a considerable scale.

Rapid Development of a Frog.—Dr. M. L. Sethi, of Government College, Hoshiarpur, India, has made some interesting observations on the rapidity of cellular development and of the attainment of the larval stage of *Rana tigrina*. Dr. Sethi states that the frogs spawn in the early hours of the day during the breeding season; the morula stage is reached within an hour and a half after the eggs are laid; epibolic gastrulation at the end of six and a half hours; and the neural plate and folds appear in about ten hours. The larvæ hatch out within twenty-four hours. This should be compared with the developmental history of the English frog, which takes usually a fortnight to reach the corresponding larval stage. Dr. Sethi further mentions that the external gills appear within a day after hatching and hind-limbs sprout three days after and fore-limbs two days subsequent to this period. The metamorphosis is completed in thirty-eight days while in Great Britain frogs take from seventy-seven to eighty-eight days. The development in a species of *Bufo* found in Hoshiarpur is similarly rapid.

Chromosome Constitution of *Sphenodon*.—Mr. R. D. Keenan (*J. Anat.* **72**, pt. 1, 1932) has investigated the chromosomal formula of *Sphenodon* and concludes that it has 36 chromosomes, 12 atelomitic chromosomes which are V-shaped, 18 telomitic chromosomes which are rod-shaped and six microsomes. Applying the theory of Robertson concerning the formation of V-shaped chromosomes to those of *Sphenodon*, the author concludes that the primitive number of chromosomes in Reptilia is 48, and he shows how the chromosomal formula of the living members of this group, which have been investigated, can be derived from this primitive number, principally by a reduction in the size of the individual elements and by a fusion of the elements in pairs or threes. The work of Painter has led him to the conclusion that the primitive number of chromosomes in the eutherian mammals is also 48, and that, though the type number in the marsupials appears to be 24, the total amount of chromatin seems to be about the same in the two groups. The significance of the number 48 as the typical primitive number in both Reptilia and Mammalia is commented on.

Effect of Length of Day on the Flowering of Plants.—Dr. M. A. H. Tincker, of the Wisley Laboratories, has two papers in the *Journal of the Royal Horticultural Society*, vol. 57, pt. 2 (pp. 321-325 and 326-331) dealing with the effect of the length of the daily light period on the growth of various plants. *Sedum spectabile*, *Saxifraga decipiens* var. *bathoniensis*, *Anchusa italica* and the tulip 'William Pitt' all behave similarly. They are 'long day' plants and flower earliest when exposed to the normal length of day in summer. A series which had twelve hours of daylight supplemented by five hours of weak artificial light behaved very similarly to the full daylight controls, but it was demonstrated that the weak artificial light was of no direct value for the formation of food in the leaves. Two other series which were exposed to twelve hours and six hours daylight respectively remained vegetative or flowered later than the controls. The other paper reports the results of studies on the rate of tuber formation. Several plants are mentioned which produce tubers when the daily period of light in summer is reduced to 10–12 hours. When the rate of translocation of foodstuffs to the tubers is represented as 100 for the controls, it is 60 for plants exposed to 12 hours daylight and 5–7 hours weak electric light, 130 for 10–12 hours daylight and 22 for 5–6 hours daylight. The effect of potassium economy is considered along with photo-period in its relation to the formation of tubers.

Igneous Complex of the Bushveld.—The great Bushveld complex of the Transvaal is universally recognised as the most spectacular manifestation of igneous activity to be seen anywhere in the world. The memoir on which Dr. A. H. Hall has been engaged for many years is now published (Geol. Survey S. Africa, Mem. 28, pp. 554, with coloured geological map) and a vast collection of field and laboratory data which petrologists have been eagerly awaiting is now available for digestion and discussion. Minor outpourings of felsitic rocks are found in the Rooiberg series at the top of the Transvaal system. A widespread felsite-granophyre composite followed, the upper extrusive portion remaining roofless. It is not yet clear whether the norite came next, to be followed in turn by the Red Bushveld granite, or whether the granite was emplaced before the norite. This is the outstanding problem that remains unsettled. More or less *pari-passu* with the intrusion of the norite magma the floor, made up of the Pretoria series, was injected by basic sheets. During the cooling and consolidation of the norite, thoroughgoing differentiation occurred with consequent highly developed pseudo-stratification of the crystalline accumulates, and at the same time slow and long-continued basining of the floor took place as a result of load above and magmatic adjustments in depth. Intense metamorphism of the rocks of the roof and floor is ascribed mainly to the action of the norite. Following widespread erosion of the complex, eruptive activity began afresh during the period between the close of the Waterberg and the beginning of the Karroo. The products included basic and alkaline sheets and dykes culminating in a number of plugs, stocks or ring-intrusions of alkali rocks of which the Pilandsberg is the most famous. The final chapter of the memoir is devoted to the mineral resources of the Bushveld, most attention being given to the occurrences of platinum.

Subsidence of London.—The various factors that may be involved in the subsidence of London as revealed by recent re-levelling have been enumerated with comments in a paper by Capt. T. E. Longfield (Ordnance Survey. Professional Papers No. 14. "The Subsidence of London". 2*s.* 6*d.*). These influences are as follows: (1) a general and gradual lowering of the land surface in the south-east of England, of which there is some evidence from the level of Roman remains of habitation. (2) A more local subsidence of the London area, especially in central London, of which there is measurable evidence at least since 1865. This appears to be confined to the thickly built-over areas where gravel or alluvium overlies the clay and may be due to the waterproof covering of stone, cement and asphalt that allows the underlying surface to drain and so contract. (3) A seasonal subsidence and uplift caused by changes in the water-content of the London clay. This is evidenced in disturbances in walls after a long dry spell. (4) Subsidence caused by the draining or pumping of water and sand from the gravel, which is known to disturb adjacent buildings. (5) Rhythmic land movement due to fall and rise of tide. Records show that Waterloo Bridge and the County Hall, Westminster, thus rise and fall. (6) Possible subsidence due to underground tunnelling, which may cause local sinking but not a widespread subsidence.

Limiting Static Friction between Lubricated Surfaces.—A paper by Sir William Hardy and M. Nottage (*Proc. Roy. Soc.*, Nov.) describes measurements of the limiting static friction between lubricated surfaces applied to the study of the behaviour of adsorbed layers. The measurements were made using a spherical sliding face of mild steel on a mild steel plane, and it is assumed that the lubricant is reduced to two primary layers with the surface of slip between them. The lubricants were solutions of wax or palmetic acid or hexadecyl alcohol in medicinal paraffin, and the temperature variation of the limiting friction was observed. The behaviour is different for the case in which the surfaces and the lubricant are brought together at the temperature of measurement and for the case when the lubricated surfaces are heated or cooled through a temperature range. In the latter

case, the curve depends on the temperature at which the oil is first applied to the surfaces. The authors discuss their results in terms of the 'availability' and 'accessibility' of the dissolved component to the surface. The former is the fraction of the surface covered by solute molecules when the surfaces are brought together; the latter represents the power of the solute molecules to seize adsorption surface when the conditions are changed. The accessibility depends upon the previous history of the system.

History of Terrestrial Magnetism.—*Terrestrial Magnetism and Atmospheric Electricity* for June contains an article of great interest, by Dr. A. Crichton Mitchell, entitled "Chapters in the History of Terrestrial Magnetism". It consists of a very condensed discussion (25 pages) of the discovery of the directive property of a magnet in the earth's field, and of the application of this property to the nautical compass. The discussion is based on the author's re-examination of the very extensive literature bearing on the subject: it is followed by more than three hundred bibliographical references and notes (occupying 15 pages of small print), referring, as a rule, only to original sources of information, almost all of which have been consulted or verified. The final conclusions arrived at are as follows: (*a*) while it is possible that the Chinese were acquainted with the directive property of a magnet by A.D. 1093, they made no further use of that property for at least two hundred years thereafter. (*b*) There is no evidence of the origin of any such knowledge among the Arabs, and it is improbable that they transmitted any information on the matter to Europe, their earliest mention of the compass being nearly half a century after its first mention in Europe. (*c*) The compass was in use in western Europe by A.D. 1187, and taking into consideration the fact that the directive property must have been discovered much earlier, it is most probable that a knowledge of that property, and its application, in western Europe was of independent origin and as early as, if not earlier than, that in China. A specially interesting passage describes the strange historical episode of the attribution of the invention of the mariner's compass to a non-existent person, Flavio Gioja, in 1302; a statue to the mythical Gioja has been erected in the Exchange at Naples, and the six hundredth anniversary of his supposed discovery was celebrated at Amalfi in 1901. The exposure of the legend, it may be added, is due to a distinguished Italian historian, Bertelli.

Astronomical Topics

Origin of the Planetary System.—Dr. H. Jeffreys has published a further paper on this subject (*Mon. Not. Roy. Ast. Soc.*, Oct.). He replies to some criticisms raised by Prof. F. Nolke on the theory that the system arose from the collision of a star with the sun; as regards the probability of such a collision, he shows from Prof. Nolke's own figures that such a collision should occur about once in 10^8 years, so that there may be about twenty systems younger than our own. Dr. Jeffreys points out that his revised theory is the only one that gives quantitative results for the rotations of the sun and planets that are of the right order of magnitude. He quotes a statement made last year by Prof. E. W. Brown that the accepted planetary theories as regards secular variations cannot be treated as valid for periods exceeding (say) ten million years; as the planetary system is probably thousands of millions of years old, it is quite possible that the present eccentricities of orbits might have been brought about by purely gravitational methods, without having recourse to resisting medium. He notes the difficulty in explaining the origin of the satellites of Mars, and suggests that they may be captured asteroids. But he makes a slip in stating that "this hypothesis has been strengthened by the discovery of a number of asteroids with mean distances less than that of Mars." There are many asteroids with *perihelion* distances less than that of Mars, but Eros, and possibly the newly discovered 1932 *HA*, are the only ones with smaller mean distances.

A Spectroscopic Study of the Brighter Stars of Type B_e.—Vol. 4, No. 13, of Publications of Michigan Observatory contains a paper on these stars by Mr. D. B. McLaughlin. They are stars that have bright emission lines; many of the stars are either known variables or suspected of variability. One of the aims of the present investigation was to test whether the ratio of brightness of the emission lines to that of the neighbouring continuous spectrum is constant in each star; another test applied was to compare the intensity of the red and violet components of bright double lines. Some of the stars on the list show variation in both the above ratios (they are denoted in the paper as the E/C and the V/R ratios) but as a rule, marked variation in one of the ratios is accompanied by steadiness in the other. Some of the stars lose their emission lines altogether for a portion of their cycle. Pleione in the Pleiades is stated to have had them in 1906, but they have not been observed since then; *f'* Cygni lost them for a time and then regained them. The question whether the variation in these stars is due to binary character is examined. One star on the list, Beta Lyrae, is a known binary. Another one, Upsilon Sagittarii, was supposed for a time to be a very massive binary; this was, however, questioned by Prof. Plaskett, and the present paper supports his view; it is suggested that the broad lines are widened by rotation, while the sharp ones originate in an outer shell of gas, at some distance above the photosphere. The article is accompanied by some enlargements of spectrograms, to illustrate the changes described.

Nautical Almanac Tables.—The Nautical Almanac Office is publishing a series of tables, which will be of great use to astronomical computers. Heliocentric co-ordinates of all the planets except Mercury are given from 1900 to 1940; for Jupiter and Saturn they go back to 1797. All positions are referred to the equinox of 1950, this uniformity being a great convenience in dynamical investigations. There are also extended precession tables for reducing data to the equinox of 1950. Coefficients are given for commencing investigations on the motions of heavenly bodies by the method of mechanical quadratures. This was the method used by Dr. P. H. Cowell for Jupiter's eighth satellite, and for Halley's comet.

Anniversary Meeting of the Royal Society

AFTER reference, according to "pious custom", to the work of the two foreign members and fourteen fellows of the Royal Society who died during the past twelve months, Sir Frederick Gowland Hopkins, in his anniversary meeting address on November 30 as president of the Society, made a plea for the establishment of chairs in the history of science. Individual scientific achievement is stored in fewer memories than is great literature, partly because it is but a step in the progress of knowledge. The perspective of history is specially valuable in maintaining sound judgments in these days of revolutionary views. Christopher Wren provides an example of a man whose services for experimental science have been overshadowed, except for the few, by other achievements. The tercentenary of his birth occurred during the past year, and also that of Antony van Leeuwenhoek and of Marcello Malpighi, both of whom were also associated with the Royal Society during its early years. The number of tercentenaries of original and early fellows of the Society falling during a small span of years makes it impossible to organise a public celebration of each such event.

Sir Frederick stated that the Society is to receive an important benefaction for the support of qualified investigators. Shortly before his death, Mr. Gordon Warren allocated to the Society the sum of £1,400 a year for seven years for the maintenance of a research professorship or two research fellowships. Two Warren research fellows, Dr. A. J. Bradley and Dr. W. Hume-Rothery were accordingly appointed last June. Mr. Warren died suddenly, leaving a large sum of money, subject to a life interest, which is ultimately to be devoted to science, and the Royal Society is to be consulted as to its disposal.

The Royal Society Mond Laboratory at Cambridge (NATURE, Feb. 13, 1932, p. 224) is practically complete and will be opened in February.

We print below extracts from the president's remarks in bestowing this year's medals.

Presentation of Medals

COPLEY MEDAL, awarded to DR. G. E. HALE

Dr. Hale's first notable achievement was in 1892, when he brought the spectroheliograph to success. This instrument gives a picture of the sun by the light of one spectrum line, and allows the bright clouds of hydrogen and calcium in the upper regions of the sun's atmosphere to be photographed as projected on the disc. The idea had been suggested and tried much earlier, but Hale was the first to make a workable automatic instrument of this kind. About the year 1895 Hale organised the building of the Yerkes Observatory and of the great refracting telescope there, to which an improved spectroheliograph was adapted. To this period belongs also a masterly investigation of the spectra of certain faint red stars. This was the precursor of a much larger enterprise, the Mount Wilson Observatory, with many unique instruments, such as the 150 ft. tower telescope and the 100 in. diameter reflector.

At the Mount Wilson observatory Dr. Hale made his great discovery of the Zeeman effect in sunspots by observing the circular polarisation of the edges of the broadened spectrum lines, where they cross the spot. Regions of thousands of miles across were thus shown to be the seat of intense magnetic forces, comparable in strength with those used in the dynamo machine. This discovery has been developed in many important directions.

In recent years Dr. Hale has developed the spectrohelioscope, an instrument depending on the persistence of vision, which allows us to observe transient phenomena scarcely accessible to the spectroheliograph. We may confidently expect that it will contribute to clearing up the mysterious relations between terrestrial magnetism and solar phenomena.

RUMFORD MEDAL, awarded to PROF. FRITZ HABER

Alike at Karlsruhe, where he went in 1894, and at Dahlem from 1911 to the present time, Haber has inspired schools of great and highly productive activity. His own early studies of the oxidation and reduction of organic substances by electrochemical methods, and the numerous electrochemical studies which followed this important work, such as his researches on gas cells, on the rate of ionic reactions, on the electrolysis of solid salts, on the velocity of reaction at electrodes, and on the use of the glass electrode, have enormously advanced progress in this branch of science.

Haber's profound study of the thermodynamics of gas reactions culminated the synthetic production of ammonia. With van Oort, he carried out a preliminary investigation on the ammonia equilibrium, but owing partly to discrepancy with figures obtained by application of the Nernst theorem, further experiments were made with le Rossignol in 1906. In 1908 satisfactory catalysts had been found and the synthesis of ammonia achieved. The far-reaching technical results of these careful thermodynamical studies are in themselves a monument to Fritz Haber; one of the German factories alone can produce more than 1,000 tons of ammonia daily. The influence of this on the food supply of the world is of the highest importance.

Haber's wide interest, combined with his insight and grasp, made possible the application of modern physical principles to a wide range of problems of physical chemistry, such as the determination of molecular structure and calculation of lattice energies, the nature of the amorphous state, chemiluminescence, reaction kinetics and electron emission during chemical reaction. During the past few years, Haber has been successfully making manifest the rôle of the hydrogen atom in combustion processes.

ROYAL MEDAL, awarded to PROF. R. ROBINSON

Prof. Robert Robinson has won world-wide distinction by his work in many branches of organic chemistry, particularly by his elucidation of the structure of plant products and of their phytochemical synthesis. No living organic chemist has displayed a greater versatility of thought and of method. His more recent researches on the distribution, the constitution and the laboratory synthesis of the anthocyanins, the pigments of flowers, fruits and berries, have excited the keenest interest of chemists and biologists. His work on the structure of alkaloids and the syntheses to which it has led

him are classical in character. The synthesis of tropinone has been referred to as the most elegant in chemical literature. On the mechanism of chemical reaction he has contributed theoretical ideas which, of interest both to chemists and physicists, have opened new avenues of investigation.

ROYAL MEDAL, awarded to PROF. E. MELLANBY

Prof. Edward Mellanby showed that the central factor in the development of rickets is a defective diet. He introduced experimental methods, produced rickets by feeding animals on a deficient diet, and showed that the missing factor was of the nature of a fat-soluble vitamin. Previously only clinical observations had been recorded, on the effect of sunlight, and on other supposed factors; there was no sound evidence that a material substance regulates the calcification of bone. It was Mellanby's fundamental work which during the last decade made possible numerous and important researches by others, culminating a year ago in the recognition of the material substance (vitamin D) as an isomeride of ergosterol.

Mellanby's later researches suggest hitherto unsuspected problems, though their very novelty has so far precluded the clear definition and finality which is now the outcome of his earlier works. Thus he has shown the adverse effect, in certain circumstances, of an excessive amount of cereal germs. In the absence of vitamin A the latter, and particularly ergot of rye, produce a degeneration of the spinal cord. Incidentally, this observation provides a satisfactory explanation of the peculiar and hitherto obscure incidence of convulsive ergotism in man.

DAVY MEDAL, awarded to PROF. R. WILLSTÄTTER

Prof. Willstätter's earlier studies gave us our present complete knowledge of the molecular structure of atropine and cocaine, and his analytic and synthetic studies of these alkaloids have had important sequels in systematic organic chemistry and in pharmacology. He then proceeded to a series of ingenious researches bearing on the problem of quinonoid character and on the benzene theory and these led in succeeding years to further work on cyclic compounds of much general interest. He early showed himself to be a master of method in organic chemistry. His name will, in the future, bring most readily to mind the discovery of magnesium in chlorophyll, and this, along with the painstaking and monumental investigations of the structure of chlorophyll and the blood pigment, represents the high-water mark of his achievement. Coupled with this work was a series of valuable contributions to the study of carbon assimilation. Equally novel and brilliant were his researches on the anthocyanin pigments of flowers and blossoms; a whole new chapter of organic chemistry was written. Finally, the studies on the enzymes have added greatly to our positive knowledge, enabled us fully to estimate the difficulty of the task, and laid down the lines on which future work must proceed.

DARWIN MEDAL, awarded to DR. C. E. CORRENS

Dr. Correns was one of the three botanists (the other two being Tschermak and de Vries) who in 1900 independently brought to the notice of biologists the fundamental work of Mendel, which had remained neglected since 1865. Since 1900 he has been actively engaged in developing the science of genetics. In 1902 Correns was the first to elucidate the remarkable phenomenon of the production of red flowers in the first cross between two white-flowered races of *Mirabilis*. He was also the first to show in the crossing of two species of *Mirabilis* that if very numerous genetic factors relating to small morphological differences are present, it is impossible to establish segregation in the F_2 generation, unless very large numbers are available. This explains the appearance of supposed 'constant' hybrids, as has since been shown by other observers in numerous instances.

Correns was also the first experimenter clearly to establish inheritance which did not follow Mendelian rules. Thus he showed in *Mirabilis* and other plants that variegation of the leaves depending on the failure to develop chlorophyll, is inherited only through the mother because the plastids which carry the chlorophyll are present in the egg cell and not in the sperm. Again, he demonstrated that paternal characters shown by extra-embryonal parts of fruits produced by crossing (so-called 'xenia') were always limited to the endosperm, that is, to the food tissue formed by the fusion of a second sperm with nuclei belonging to the maternal parent. But his most important work is probably the elucidation of the inheritance of sex. By crossing a monœcious with a diœcious species of *Bryonia*, he showed in 1907 that the females were all homozygous and the males heterozygous for the sex factor. The generalisation that one sex is always homozygous and the other heterozygous corresponds with the normal approximately equal distribution of the sexes in the offspring of unisexual individuals and with the differences between the chromosomes of the sex-cells, and is now well-established. Deviation from the equal distribution of the sexes Correns showed to be due in *Melandrium* to the more rapid action of the male-determining sperms, and this is a principle of wide application. Again, he was the first to explain the differential fertility of a generation of plants with their parents and with one another by the assumption of two distinct and inherited inhibiting substances in the stigmata of the flowers.

BUCHANAN MEDAL, awarded to PROF. T. MADSEN

Dr. Madsen's best known scientific work has been on the toxins and anti-toxins of diphtheria and tetanus bacilli and on other animal, vegetable and bacterial toxins and antigens and their antibodies. He initiated and published with Arrhenius, classical work on the theory of toxin and antitoxin combination, showing that the process resembled the combination of a weak acid and base rather than the union of a strong acid and base, as had been held by Ehrlich.

Madsen was largely concerned with the origin of the Commission on Hygiene, which he directed in Eastern Europe during the latter part of the War. Since then he has been president of the Health Committee of the League of Nations and president of the Permanent International Committee on Biological Standards, which was in great part due to his initiative.

HUGHES MEDAL, awarded to DR. J. CHADWICK

Dr. Chadwick is distinguished for his contributions to radioactivity and nuclear physics. Amongst a number of other investigations on α-, β- and γ-rays, he was the first to show explicitly about 1920 that the charge on the nucleus was equal to the atomic

number, by a quantitative study of the large-angle scattering of α-particles by selected elements, thus verifying by direct experiment the correctness of Moseley's deduction. He was associated with Rutherford, 1922–30, in a long series of investigations (1) on the anomalous scattering of α-particles by light elements, which threw the first light on the size and structure of the nucleus, and (2) on the artificial transmutation of the elements by α-ray bombardment. These experiments showed that at least twelve of the lighter elements were transmuted with the ejection of a proton, and laid the foundations of a study which has recently so rapidly accelerated.

In 1928 efforts were started to improve the technique of these experiments by using automatic electrical counting, and methods were perfected by the end of 1930. Dr. Chadwick applied the new methods to a more detailed study of the groups of disintegration protons, especially from boron and aluminium, for which he established clearly for the first time the existence of definite nuclear α-particle and proton levels. Finally, this year, when the observations by M. and Mme. Curie-Joliot had indicated certain curiosities produced by the supposed γ-radiation from beryllium bombarded by α-particles, Dr. Chadwick immediately recognised that the effects observed could only be adequately explained by the assumption that the radiation from beryllium was of a new type—the ejection of a neutron—and by a brilliant series of experiments he confirmed this conjecture, and with the collaboration of Dee and Feather was able to establish its essential properties.

The Place of Biology in Education

THE National Conference on the Place of Biology in Education, organised by the British Social Hygiene Council, which met at the British Medical Association House on November 1–December 3, may well prove a landmark in the history of education in Great Britain. When five Ministries, the chairmen of the Advisory Council to the Department of Scientific and Industrial Research, of the Medical Research Council, and of practically every educational body of importance, appear among the patrons, and when administrators and leaders of research such as Viscount Chelmsford, Sir Walter Fletcher, Sir Richard Gregory, Sir William Hardy, Prof. A. V. Hill, Sir Michael Sadler, Sir Amherst Selby-Bigge, and Sir Stephen Tallents appear side by side with men of high standing in the educational world, the public cannot dismiss their arguments as unimportant.

Since the purpose of the Conference was not to pass resolutions but to drive home the fact that competent judges in the spheres of national and imperial affairs, of research, of teaching, and of sociology are agreed upon the urgent necessity of providing the administrator, the social worker, and the ordinary citizen with a biological background, it would be difficult to imagine a gathering of greater weight, or one more likely to produce results.

Since it is hoped that a full report will shortly be available, it is as unnecessary as it would be impossible to attempt a detailed summary; but such an utterance of authoritative opinion certainly calls for a record of the general impression it left behind. The earlier speeches laid a firm foundation. Lord Chelmsford's account of the Prime Minister's committee over which he presided fittingly reminded those attending the Conference that they were deliberating matters of world-wide importance. Besides dealing with the specialist, the report of that committee emphasises the cultural value of biology, and states that no boy should leave school without some knowledge of it. Sir Michael Sadler, setting evolution against the background of the absolute, widened the horizon, and insisted that biological education demands a philosophy of life. Sir Walter Fletcher carried the theme further in a noble progression. Biology is essential in a mechanical age because it answers the human needs of utility, beauty, and worship. By putting utility lowest and then proceeding to show how neglect of biological research has lost us the sugar trade of the world, destroyed the trade in vegetable dyes, and brought us up against social problems even more anxious, while English wheat-growing has been saved by such research, he gave fitting emphasis to the higher needs. Prof. A. V. Hill laid stress on the fact that all science is one, and urged that since civilisation expresses the activity of a living organism, man, biological knowledge is essential to its understanding. Then speaker after speaker, from many-sided experience, while emphasising the danger of such specialisation as has overtaken chemistry and physics, impressed the truth that to be totally ignorant of biology is to be an incompetent citizen and a dangerous legislator.

More and more clearly emerged the demand for two kinds of biological training. The specialist is required for many purposes and the need is a growing one despite the economic set-back which has temporarily narrowed or closed some avenues; though if the specialist is not thoroughly trained in chemistry and physics his usefulness is greatly restricted. But unless every single citizen is educated in the understanding of biological ideas, then problems of industry, economics, population, and the mentally unfit, may prove too much for us. On every side the biological aspects of citizenship grow more significant and the need for biological education more urgent.

The fundamental note of the Conference was the recognition of this need, and of the corollary that in every stage of education, and for girls as well as for boys, biology must have its place. In the primary schools there has been little progress. Here Sir Richard Gregory wisely stressed the need of natural interest rather than of the illustration of scientific laws in the early stages. Other speakers showed how eagerly young children respond to teaching about the living organism.

The situation in teachers' training colleges, in central and secondary schools, in preparatory and public schools came under review, and the cry for more and better biology, biology on broader lines, was everywhere the same. Not least significant was the complaint of the headmaster of a preparatory school that there would be time for natural history if many parents did not so neglect early education that their sons reached the preparatory school unable to write grammatically or to do simple arithmetic. Nevertheless, it became clear that, in the opinion of the Conference, the preparatory schools could do an immense amount for the public schools by

encouraging Nature study. Not only the biological teaching, but also that important element, the school natural history society, would derive immediate benefit.

The representatives of the Headmasters' Conference spoke with a divided voice, suggesting that insofar as any unfavourable or reactionary views were expressed, they were individual rather than collective. While every sympathy attached to the warning against an over-loaded curriculum, and to the claim that to neglect chemistry and physics would be disastrous to biology, the general sense of the Conference seemed to be that rearrangement without overloading is both possible and necessary. Dr. Vaughan's timely warning that demands for biology should not be based on moral grounds found acceptance; on the whole, the Conference, while impressing the gain of biological teaching in which reproduction fell into its right perspective among the other functions of the organism, seemed to feel that any bias of the ordinary biological work in the direction of sex instruction is undesirable, though in some cases *ad hoc* courses, specially safeguarded, may prove helpful in day schools.

In fine, the National Conference on the Place of Biology in Education has pointed to a grave omission in the cultural training of citizens with a unanimity and an authority which cannot be disregarded. The situation must be put right; and the schemes submitted by Sir J. Arthur Thomson and others suggest a method for the earlier stages.

The nation owes a debt of gratitude to those who have helped in thus directing attention to a failure which is little short of disastrous, and in supplying a hope for the future. S. A. McDOWALL.

Alchemy and Alchemists*

IN a narrow sense, alchemy may be interpreted as the pretended art of transmuting the baser metals into silver and gold. In a wider sense it may be defined as the chemistry of the Middle Ages: according to Liebig, indeed, alchemy was never anything but chemistry. In its broadest aspect, it appears as a system of philosophy which claimed to penetrate the mystery of life and the formation of inanimate substances: it was thus a complex and indefinite blend of chemistry, astrology, philosophy, magic, mysticism, theosophy, and other ingredients.

To the philosophic alchemists, the efforts made by the adepts to transmute metals were mainly of interest as attempts to prove the truth, on the material plane, of an all-embracing philosophic system. The despised 'puffers', at the other end of the scale, were materially-minded seekers after gold. There were still others who interpreted the doctrines of alchemy in terms of mystical theology: thus, the celebrated Canon Ripley of Bridlington, in the prologue to his "Twelve Gates" (1471), wrote: "O Unity in the substance, and Trinity in the Godhead . . . as Thou didst make all things out of one chaos, so let me be skilled to evolve our microcosm out of one substance in its three aspects of Magnesia, Sulphur, and Mercury."

Heinrich Khunrath's quaint illustration of the alchemic citadel (1609), and Mylius's elaborate representation of the analogy of the alchemic microcosm to the macrocosm (1620) are examples of alchemy in its broadest interpretation, as are also the numerous illustrations which were collated in the "Viridarium Chymicum" in 1624 by Daniel Stolcius, a young Bohemian student. From such examples of its literature and iconography, alchemy appears as a jumble of natural and moral ideas, a confusion of objective facts and subjective notions, incorporating the fundamental principles of animism, and exhibiting ill-defined connexions with the story of the Grail and other confused records of forms of worship, superstitions, occultism, and the like.

Among the reputed adepts, none had a more circumstantial and romantic history than the Scottish alchemist, Alexander Seton, who has been termed "the chief martyr of alchemy". A century before his time, James IV of Scotland was interested in alchemy as a means of gold-making and of healing disease. His chief alchemical assistant was John Damian, who was created Abbot of Tungland in Galloway, in 1504, "so that he might have more leisure to carry on his experiments". Details of the expenses incurred in these experiments, many of which were conducted in the Castle of Striveling (Stirling), are still extant and form very interesting reading. The poet Dunbar said of Damian that "this Dignitary never chose to go to Mass though warned by the holy Bell"—apparently because he feared the defiling effect of the laboratory smoke upon his costly religious vestments.

"This tyme," says an old record, "thair wes ane Italiane with the King, quha wes maid Abbott of Tungland, and wes of curious ingyne. He causet the King believe that he, be multiplyinge and utheris his inventions, wold make fine golde of uther mettall, quhilk science he callit the quintassence; quhairupon the King maid greit cost, bot all in vaine. This Abbott tuik in hand to flie with wingis, and to be in France befoir the saidis ambassadouris; and to that effect he causet mak ane pair of wingis of fedderis, quilkis beand fessinit apoun him, he flew of the castell wall of Striveling, bot shortlie he fell to the ground and brak his thee bane; bot the wyt theirof he asscryvit to that thair was sum hen fedderis in the wingis, quhilk yarnit and covet [yearned and coveted] the mydding and not the skyis."

*Substance of a paper presented by Prof. John Read to the Folk-Lore Society on November 30.

University and Educational Intelligence

BIRMINGHAM.—Mr. Frank Postlethwaite has been appointed James Watt fellow for the current session.

CAMBRIDGE.—Prof. B. L. van der Waerden, of the University of Leipzig, has been appointed Rouse Ball lecturer for the year 1932–33, and Prof. Hans Geiger, of the University of Tübingen, Scott lecturer for the year 1933.

The General Board recommends that an Alfred Marshall lectureship be established in the Faculty of Economics and Politics.

Sir Arthur Hill, director of the Royal Botanic Gardens, Kew, formerly scholar and fellow, has been elected to an honorary fellowship at King's College.

Dr. H. R. Hulme has been elected to an unofficial Drosier fellowship at Gonville and Caius College for research in mathematical physics. Dr. Hulme was placed in the first class of Part I of the mathematical tripos in 1927 and was a wrangler with distinction in 1929. He won a Smith's prize in 1931 and was elected an Isaac Newton student in 1932.

LONDON.—A University postgraduate travelling studentship of the value of £275 for one year has been awarded to Mr. W. B. Mann, Imperial College of Science and Technology, who proposes to carry out research on rarefied gases, in particular to determine the molecular conductivities, at Copenhagen.

THE opening ceremony in connexion with building extensions at the Northampton Polytechnic Institute, St. John Street, E.C.1, was performed by H.R.H. Prince George on the evening of December 2. Nearly 90 per cent of the 3,000 students of the Polytechnic attend evening classes. There are also important day departments providing courses in engineering and ophthalmic optics. The former are recognised by the University of London for the purpose of internal degrees, as are also courses of similar type conducted in the evening. The extension occupies part of a site with street frontage on three sides facing the main Polytechnic building. In addition to further lecture rooms and class-rooms, accommodation is provided for the chemistry and horological sections; there are also a large workshop for instruction in lens-making and automobile laboratories. The building, which, apart from site, furniture and equipment, has involved an expenditure approximating to £45,000, comprises basement, ground floor and four stories above. The total floor area is approximately 28,000 sq. ft., of which nearly 20,000 is directly 'useful'. Rooms occupied by the chemistry section include lecture room and two laboratories for general chemistry on the first floor, with laboratories for fuels, electro-deposition, metallurgy and metallography immediately above. The watch and clock-making department occupies the fourth floor and comprises separate workshops for clock-making and watch-making, timing laboratory, master clock station and drawing office. The provision of these additional premises is designed to permit of considerable expansion within the main building of laboratory and workshop accommodation for engineering and physics.

Calendar of Geographical Exploration

Dec. 12, 1639.—Exploring the Amazon

Pedro de Teixeira arrived at Pará after his journey to Quito. Teixeira had become Governor of Pará in 1618 and had ascended the Amazon and its tributary, the Tapajos, in quest of slaves. In June 1637 two friars had launched a boat on the Napo and thence sailed on the Amazon to its mouth. Their adventure suggested the possibility of navigating the Amazon, and Teixeira set out late in 1637 to explore the river route to Quito. The Portuguese explorer slowly and with difficulty accomplished the journey against the current. From Quito he again returned by the river, noting the confluences of its tributaries. Information was also gained of the connexion with the Orinoco by means of the Cassiquiari, though this news was received with incredulity.

Dec. 13, 1577.—Sir Francis Drake

Sir Francis Drake sailed on his circumnavigation of the globe, the first carried out by an Englishman. He was apparently commissioned to examine the coast of Terra Australis as shown on the map of Ortelius 1570. But he certainly knew of the insular character of Tierra del Fuego and quite probably rounded Cape Horn; thus his journey disproved the map. He also reported a good bay on the west coast of America in lat. 43° N. This report, like that of Juan de Fuca, who was said to have discovered, in 1592, a strait in 47° N., greatly stimulated the search for a north-west passage.

Dec. 13, 1835.—Exploration of the Irrawaddy

Capt. S. F. Hannay arrived at Katha on the Irrawaddy. He proceeded to Bhamo and explored the Mogaung River. From Mogaung he went to the amber mines of the Hukawng valley, but the miners distrusted his Burmese escort and he returned by the route along which he had come to Ava. Until his time Ava had been the farthest point reached on the Irrawaddy. Hannay's voyage suggested that there was little possibility that the Tsang-po (Brahmaputra) flowed into the Irrawaddy, as was supposed by some to be the case; in 1886 Needham definitely proved that there was no connexion between the two rivers.

Dec. 14, 1911.—Roald Amundsen

Roald Amundsen, the famous Norwegian explorer, reached the south pole and remained there taking observations until Dec. 16. In 1903–6, Amundsen had achieved the navigation of the north-west passage, which had for centuries baffled explorers. A small sealing sloop, the *Gjöa*, was fitted with a motor and strengthened to withstand ice. She left Christiania on June 17, 1903, with six men only, passed through Lancaster Sound down the west side of Boothia Felix and wintered in Gjöa Harbour, King William Island. Here the ship remained for two years and sledging excursions were made to the magnetic north pole and the coast of Victoria Island was charted to 72° N. The *Gjöa* proceeded westward, but was frozen in off King Point, where a third winter was passed. On July 11, 1906, she got free and then sailed through Bering Strait into the Pacific. Thus at last was realised the dream of early mariners. In 1918–21 Amundsen made the north-east passage, wintering three times on the Siberian coast. On May 11, 1926, two days after Commander Byrd had flown from Spitsbergen to the north pole and back, Amundsen flew in the airship *Norge* from Spitsbergen across the pole to Teller, Alaska, a distance of 3391 miles in 72 hours. Amundsen left Bergen in an aeroplane on June 17, 1928, to search for Nobile after the wreck of the airship *Italia*, and was never heard of again.

Dec. 17, 1837.—Sir George Grey in Australia and New Zealand

Sir George Grey started an inland journey from Prince Regent River in an endeavour to reach the Swan River, but was unable to do more than explore the Glenelg and Prince Regent Rivers, owing to a wound received in a struggle with natives. In 1838 he attempted an exploration of the coast north and south of Shark's Bay, but his three boats were wrecked and the party had to tramp overland from Cantheaume Bay to Perth, a distance of 300 miles. Grey pushed on ahead to bring relief to the party and walked into Perth on April 20, so changed by suffering that his friends did not know him. The expedition resulted in the discovery of some ten rivers, including the Gascoyne, Murchison, Greenough and Irwin, as well as parts of the Darling and Victoria Mountains. In 1841 Grey became Governor of New Zealand where he took a keen interest in the Maori, who in turn were devoted to him. His scholarly collection of their legends and myths has become a classic.

Societies and Academies

London

Geological Society, Nov. 9.—**C. T. Madigan:** The geology of the Western MacDonnell Ranges, Central Australia. The sections of previous investigators, including those of the Horn Expedition, H. Y. L. Brown, and L. K. Ward, are correlated, and the formations are traced and mapped throughout the area. The stratigraphical position and actual location of the very important Horn Valley, with its Ordovician fossils, are finally established. A new Ordovician fossil locality in the James Ranges is recorded, and the first geological account of the Waterhouse Range is given. The Central Australian formations are reclassified and the age of the beds is fully discussed.—**T. N. George:** The Carboniferous Limestone series in the west of the Vale of Glamorgan. The stratigraphical sequence in the Avonian is comparable with that established in Gower to the west by Dixon and Vaughan, and in the district around Ruthin and Miskin to the east by Dixey and Sibly. The normal succession of zones is displayed, without any marked departures from the characteristic lithological types of each. As a whole, the series was probably deposited in slightly deeper water than the Gower Series, and dolomite is poorly developed. The rocks over the greater part of the area are folded into a pitching anticline, the Candleston anticline, the axis of which falls eastward. Over the western part of the area, around Porthcawl, the strata are almost horizontal, only D_1 being exposed. A number of minor north-and-south faults traverse the rocks, at least one of which is a tear of post-Triassic age.

Physical Society, Dec. 2.—**Lewis F. Richardson:** Time-marking a kathode-ray oscillogram. Time marks have been arranged as little blurs or gaps in the trace, by periodically unfocusing the electron stream. The current in and voltage across a conductor can thus be recorded together with the time on a single oscillogram.—**J. F. Herd:** The generation and reception of wireless signals of short duration. In the use of short-duration signals for investigation of the ionosphere, it is convenient to emit the signal pulses at a controlled rate and to receive them on an oscillograph giving temporal discrimination between the arrival of the ground ray and that of subsequent echoes. Simplification of recording technique can be obtained if, at the receiver, an oscillograph of the cathode ray type is used in conjunction with a time-scale voltage of which the rate of recurrence is exactly the same as that of the emitted impulses. The paper describes methods of utilising the common frequency of an A.C. supply network to secure such synchronisation.—**R. Naismith:** A comparison of the frequency-change and group-retardation methods of measuring ionised-layer equivalent heights. Measurements are conducted under as varied conditions as possible. The results appear to confirm the theoretical investigation recorded by Appleton in 1928. The apparatus used to measure the amount of the frequency change employed in the measurements is described.—**H. L. Wright:** The influence of atmospheric suspensoids upon the earth's magnetic field, as indicated by observations at Kew Observatory. Changes in the electrical resistivity of the air and in the potential gradient may be associated with changes in the concentrations of gross particles and of condensation nuclei. Observations of these four quantities made at Kew Observatory over a period of three years indicate that resistivity depends upon the number of gross particles and of condensation nuclei, while potential gradient varies with resistivity and the number of nuclei.

Dublin

Royal Irish Academy, Nov. 14.—**L. B. Smyth:** *Cleistopora geometrica*, Milne-Edwards and Haime. Specimens of this curious Devonian coral from the type locality, Sarthe, France, were studied. Tabulæ, said by Nicholson (1888) to be absent, are demonstrated. The mural pores are shown to be straight, not tortuous. A wrinkled epitheca appears where the corallum extends beyond the supporting brachiopod shells. Separation of the index fossil of the Lower Carboniferous *Cleistopora* zone from this form is fully supported by the investigation.—**R. Lloyd Praeger:** Some noteworthy plants found in, or reported from, Ireland. Careful investigation during 1931–32 has proved in the author's opinion, that *Arbutus Unedo* is native on Lough Gill in Sligo—heretofore it has been known only from Kerry and West Cork, though place-names point to its former extension as far north as Mayo. *Cochlearia anglica* is present everywhere round the Irish coast. The claims of *Arctostaphylos alpina* and *Selaginella Kraussiana* reported from Ireland to a place in the flora are not admitted.—**R. Patten:** Observations on the cytology of *Opalina ranarum* and *Nyctotherus cordiformis*. The endoplasmic bodies in *Opalina ranarum* are flattened disc-like bodies, with the flat side generally parallel to the flattened surface of the organisms; the rod or dumb-bell-shaped forms and the irregular or spherical bodies are but two aspects of the same structure. Mitochondria are present as small spherical structures revealed by chrome-osmium techniques, and also by intra-vitam staining with Janus green. Blackened bodies, shown by Da Fano's silver method, in the outer regions of *Opalina* may be Golgi elements. *Nyctotherus* bacteria, both bacilli and cocci, are seen by various fixatives, in the cytoplasm. No Golgi apparatus has been revealed. Large numbers of smaller bodies are preserved by many methods. These as well as bacteria are Gram positive, but in spite of resemblances the former are not bacteria—they are probably modified mitochondria.

Paris

Academy of Sciences, Nov. 2 (vol. 195, pp. 725–740).—**Paul Pascal and Jean Grévy:** The action of ammonia and amines on the viscosity of collodion. The effect of ammonia on the viscosity of solutions of guncotton in ether-alcohol mixtures is a function of the time. There is, at first, a rapid increase in the viscosity followed by a decrease. Viscosity time curves are given showing the effects of increasing quantities of ammonia. The fatty amines produce a similar but more marked effect and a diagram is given showing the comparative effects of ammonia, methylamine, dimethylamine and ethylamine.—**André Haarbleicher:** Some new properties of the trajectories of points linked *à un trois barres*.—**Henry Girerd:** The measurement of the aerodynamical characteristics of a supporting wing in a plane current.—**L. Malavard:** The fundamental problem concerning the (aeroplane) wing of finite spread.—**Jacques Bourcart:** The marine deposits of the second Miocene cycle of western Morocco.—**Marc Simonet:** Chromosome counting in the

genera *Baptisia*, *Thermopsis* and *Lathyrus*. Twenty-four species of *Lathyrus* give the same number of chromosomes, 7: *Baptisia* and *Thermopsis* have the same number, 9.

ROME

Royal National Academy of the Lincei, June 19.—L. Petri: *A photoelectric method for demonstrating* Gurwitsch's mitogenetic radiations. Results obtained by a new method confirm Rajewsky's conclusion, that the radiation discovered by Gurwitsch is emitted even in complete darkness. They show, moreover, that a paste made from the germinating caryopsids of grain is less active in this respect than the whole caropsids and continues to yield the radiation for only about thirty minutes instead of for several hours.—P. Clemente: New majoration formulæ for the periodic solutions of an ordinary linear differential equation of the second order.—M. Ghermanesco: Laplace's equation. The application of Laplace's equation for a plane to a space of n dimensions is considered.—Hans Hamburger: Ribaucour's transformation and spherical representation. (1) Remarks on the general theory of Ribaucour's transformation.—M. Picone: Integral equation translating the most general linear problem for the ordinary linear differential equations of any order.—U. Cassina: The pendulum of variable length.—L. S. Da Rios: Auto-rotating rotor cylinders.—E. Martin: Method for calculating the orbit of a visual binary.—G. Agamennone: The presence of slow waves *in the preliminary phase of certain seismograms*.—G. A. Barbieri and A. Tettamanzi: New complex compounds of silver cyanide with sodium cyanide. The presence of the complex $Ag(CN)_3$ in crystalline compounds has been shown by the preparation of additive products of sodium, magnesium, and calcium argentocyanides with hexamethylenetetramine. It is now found that sodium and silver cyanides form, besides $NaAg(CN)_2$, also the compounds $Na_2Ag(CN)_3$, $3H_2O$ and $Na_3Ag(CN)_4$, $5H_2O$, both of which are obtainable in the crystalline condition.—A. Corbellini and M. Angeletti: Stereoisomerism of 2 : 2′-disubstituted derivatives of diphenyl (2). Fractional crystallisation from alcoholic solution of the brucine salt of racemic 2-[bis-phenylhydroxymethyl]-2′-diphenylcarboxylic acid yields, in larger amount, the less soluble lævo-rotatory salt.—G. Devoto: Magnetic susceptibility of the carbamides, isocarbamides, and sulphamide. Investigation of these compounds in the solid state reveals again the negligible effect of isomerism on diamagnetism, the empirical formula being of fundamental importance in this respect.—F. Garelli and G. Racciu: Triphenyl phosphate as a solvent in cryoscopy (1). Although certain compounds exhibit somewhat anomalous behaviour, the value 120 may be taken as the value of the molecular freezing-point depression of triphenyl phosphate; the value calculated by means of van 't Hoff's equation is 117·6.—A. Boni: The Miocene of Monte Vallassa.—R. Redini: The geology of Monte Pisano. Observations are described which are at variance with the conceptions of previous investigators on the stratigraphy and tectonics of this region.—Giuseppina Dragone-Testi: A new microchemical method for the separation of the cellulose in vegetable membranes. Paternò's method for dissolving cellulose for industrial purposes—digestion of the fibrous material with copper acetate solution, precipitation with sodium carbonate, dissolution of the precipitate in aqueous ammonia, and reprecipitation by acid—may be applied to the microchemical analysis of vegetable membranes.—G. Montalenti: The embryogenesis of hybrids of *Bufo vulgaris* and *Bufo viridis*.—Constantino Gorini: The coagulation of milk by the action of *Bacillus typhi* and other bacteria regarded as inactive towards milk. Chymase is widely distributed in parasitic bacteria, its formation being a normal function of the micro-organisms, independently of the presence of milk and casein. When milk which has been subjected to gentle sterilisation is poured on to vigorous agar cultures of *B. typhi*, *B. morgani*, and *B. hypolyticum*, coagulation occurs, although these bacteria are considered to be without action on milk. The enzyme occurs also in various bacteria which do not liquefy gelatine.—M. Mitolo: Action of vapours of vegetable essences and of animal aromas on medullary reflex excitability.

SYDNEY

Royal Society of New South Wales, Sept. 7.—V. M. Trikojus and D. E. White: The chemistry of the constituents of the wood-oil of the 'Callitris' pines. (1) The constitution of 'callitrol'. Chemical investigation of the wood-oil of the typical native pine of Australia, the 'Callitris' species, has shown that the substance 'callitrol' chiefly responsible for the anti-termite properties of the timber is identical with *l*-citronellic acid, this being the first record of its occurrence in Nature. H. G. Smith had considered 'callitrol' to be a phenol, but its constitution has now been proved beyond doubt. Chemical investigation of the other constituents of the oil, particularly of the sesquiterpene alcohol, guajol, is proceeding.—Burnett Mander-Jones and V. M. Trikojus: The synthesis of bases allied to coniine. (1) The preparation and pyrolysis of the allyl ethers of *N*-heterocyclic enols. The migration of the allyl group in the *o*-allyl ethers of *N*-heterocyclic enols has been studied with the object of synthesising substances allied to the alkaloid, coniine. The ethers of 4-oxy quinaldine and its derivatives have been chiefly investigated, and it has been found that the allyl group wanders invariably to carbon in various positions in the ring, rather than to nitrogen, which is contrary to the prediction of other workers. The constitutions of the re-arranged products have been proved by synthesis, and reduction has led to the preparation of bases, the physiological properties of which are being studied.—V. M. Trikojus and D. E. White: A note on the constitution of tasmanol. 'Tasmanol', occurring in the cineol-phellandrene-bearing class of eucalypts, was considered by Smith and Robinson to be a phenol. The substance isolated from the leaves of *Eucalyptus Risdonii* has now been shown to be an acid, $C_{13}H_{22}O_3$, yielding a crystalline *p*-toluidide, and a silver salt. A methoxyl group is also present. The characteristic blood-red colour yielded by the substance with ferric chloride is due to the formation of a coloured ferric salt. The elucidation of the structure is not yet complete.—F. P. J. Dwyer, D. P. Mellor, and V. M. Trikojus: The use of potassium dichromate and sodium nitrite in aromatic nitrosations. A mixture of potassium dichromate and sodium nitrite in the molecular proportions of 1 : 2, or of sodium nitrite, with a trace of the dichromate or chromate associated with a stream of carbon dioxide, can be used to introduce the nitroso group into organic molecules under extremely mild conditions. The conditions can be so arranged that the reaction occurs entirely under neutral or slightly alkaline conditions. The

reaction has been carefully followed electrometrically, using the glass electrode, for the rapid production of pure diazo-amino benzene.—A. R. Penfold and J. L. Simonsen : The essential oils of three species of *Geijera* and the occurrence of a new hydrocarbon (2). The new substance to which the name 'geijerene' has been given, possesses the formula $C_{12}H_{18}$. Unfortunately, it does not yield any crystalline derivatives. Despite the large number of experiments, no evidence has yet been obtained which would enable the authors to suggest a constitution for the hydrocarbon.

Forthcoming Events

SATURDAY, DEC. 10

BRITISH PSYCHOLOGICAL SOCIETY, at 3—Annual General Meeting at Bedford College, Regent's Park, N.W.1.

MONDAY, DEC. 12

ROYAL SOCIETY OF ARTS, at 8—(Fothergill Lecture).—Maurice E. Webb: "The Design and Construction of Buildings in Relation to Fire Risks".

ROYAL GEOGRAPHICAL SOCIETY, at 5—Dr. J. Georgi: "The Scientific Results of the Wegener Expedition to Greenland".

SOCIETY OF CHEMICAL INDUSTRY (YORKSHIRE SECTION), at 7.15—(Jubilee Memorial Lecture).—Dr. E. F. Armstrong: "Alcohol through the Ages" (to be repeated before other Sections).

TUESDAY, DEC. 13

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, at 8.30—(Harrison Memorial Lecture).—Sir Henry Dale: "Therapeutic Problems of the Future".

WEDNESDAY, DEC. 14

ROYAL SOCIETY OF ARTS, at 8—S. P. B. Mais: "The Work of the National Trust".

INSTITUTION OF CHEMICAL ENGINEERS, at 5.30—(at the rooms of the Chemical Society, Burlington House, W.1).—Conference on "Testing of Chemical Plant". Papers by A. L. Bloomfield, Prof. W. E. Gibbs and Dr. A. J. V. Underwood.

NEWCOMEN SOCIETY, at 5.30—(in the Science Museum, South Kensington, S.W.7).—Public Lecture by F. Nasmith to commemorate the bicentenary of Sir Richard Arkwright.

BRITISH PSYCHOLOGICAL SOCIETY (MEDICAL SECTION), at 8.30—Dr. John Rickman, Mrs. E. Brackenbury, Dr. William Brown and E. Glover: Symposium on "Psychology and Psychical Research".

THURSDAY, DEC. 15

UNIVERSITY OF BRISTOL, at 5.15—(Henry Herbert Wills Memorial Lecture).—Lord Rutherford: "Atomic Transformations".

CHEMICAL SOCIETY, at 8—Discussion on "The Chemistry of Sterols, with Special Reference to Ergosterol", to be opened by Prof. I. M. Heilbron.

FRIDAY, DEC. 16

ROYAL INSTITUTION, at 9—Sir George Macdonald: "Roman Wall in Scotland".

Control of Animal Pests

IT is a commonplace of biological science that no man can reckon where the repercussions of interference with Nature will end. Although examples of interference, made deliberately and with the best intention, which have turned out disastrously are abundant, new examples are always instructive if only for the reason that the lesson of far-reaching results seems to be a difficult one to learn.

No better instance of the kind is to be found than that which is developing before our eyes at the present moment. Five years ago musk-rats (musquash) were introduced into Great Britain to be bred for their fur ; some individuals escaped or were released, and now they occur in certain areas in such numbers that they form a very serious menace to agriculture and other vital interests. In the House of Lords, on December 7, the Earl de la Warr stated that in Shropshire thirty trappers are catching sixty to eighty musk-rats each week. Even so, they are but touching the fringe of the problem in that area, and there are many other areas where musk-rats are at large. Here is a grave problem to which we hope to return in these columns.

Yet another example of unforeseen results is afforded by the intensive destruction of predatory animals which has been taking place in parts of the United States, often under the auspices of Government departments. It is due in great part to the desire of increasing numbers of American citizens to shoot something, and to the difficulty, where hunters are so numerous, of obtaining something for all to shoot. The first impulse has been to organise the slaughter of the reputed enemies of game, the beasts of prey.

Already it begins to be apparent that this may be a mistaken policy. Poisoning campaigns tend directly to weed out the wrong as well as the right animals, and reports from California show how serious the threat may be to native birds as well as to mammals. This, however, is but an accident in the carrying out of a policy ; it is of greater moment that the policy itself may be at fault. In September, Science Service (Washington, D.C.) reported from Ann Arbor some of the results of an investigation carried out by Dr. Ned Dearborn, of the School of Forestry and Conservation in the University of Michigan, into the food of nine predatory animals generally reputed to be harmful to farm stock or game birds and

animals — fox, skunk, weasel, mink, 'wild cat' (lynx), opossum, raccoon, coyote and badger. For two years the food habits of these creatures have been studied, 3,000 specimens of stomach-contents have been examined, and the result suggests that the ordinary judgments usually wrong the predator. The skunk, for example, gains more than 57 per cent of its diet from insects, while birds comprise only 2·35 and eggs 0·11 per cent.

The fox, to take even a more striking example, is looked upon as the arch-enemy of the hen roost and of game birds, but according to these studies in Michigan, its food in 1931 consisted of 91 per cent mammals, of which rabbits and hares made up 81 per cent, followed, in order, by mice, rats, squirrels, deer, moles and shrews. Of the remaining 9 per cent of the total, 3·42 was insect food, 3·64 wild fruits, and only 1·12 per cent birds. In the 1930 collections, bird and egg delicacies formed a greater share of the diet, with 11 per cent. Similar results were found with regard to the other creatures tested: the larger part of their animal diet was made up of rabbits, supplemented by rats, field-mice, moles and shrews.

Dr. Dearborn holds that flesh-eating and plant-eating animals must complement one another: predators through the ages have killed off weak herbivores, thus building up strong strains, while, on the other hand, alert herbivores escape and starve out weak predators. Man upsets this balance and then tends to lay the blame on the animal group which seems to him least desirable.

With what unexpected and contrary results interference may be repaid was well shown by Mr. M. A. C. Hinton in a valuable paper on the biological principles of the control of destructive animals, recently read before the Linnean Society of London (*Proc. Linn. Soc. London*, pt. 4, p. 111, 1931–32). Two examples will illustrate his point.

The mountain lion (*Felis cougar*), once widely distributed in the United States, has been killed off until it is now represented by very few individuals. In the Kaibab National Park, in the Grand Cañon district, it has been practically exterminated, with the result that deer, deprived of their natural enemy, have multiplied without check. In 1924 there were 30,000 of them, more than the area could support; when the grass had been eaten and trees had been bared as far as the deer could reach, the animals starved. Although the numbers have now been somewhat reduced, vegetation even yet can make no headway against their depredations. Instead of protecting the deer, the slaughter of the mountain lion threatens their existence. Starvation, coupled with inactivity and over-breeding, Mr. Hinton points out, have sapped the strength of the deer, so that they may fall before the first epidemic disease or first bad year they encounter, and also suffer extermination.

The story of the rivalry in Great Britain between the old black or ship rat and the brown or Norwegian rat is well known. Neither could have survived in its hordes had we not provided it with food and shelter, and at the same time destroyed its natural enemies. But the brown rat, more hardy and robust, on its arrival in Great Britain in the early part of the eighteenth century, quietly wiped out the black rat, which since has been able only to found sporadic colonies, generally in the neighbourhood of sea-ports. By strenuous efforts, enforced by legislation and stimulated by anti-rat propaganda, the brown rat is now being ousted from many places which it used to frequent. New buildings are rat-proof from the start, old buildings are being made rat-proof.

'Brown-rat-proof' one ought to say, for Mr. Hinton reminds us that while concentrating on the destruction of the brown rat, we have been forgetting the black rat which it kept in check. His description is well worth quoting, as a warning and as a vivid picture of unlooked-for consequences. "We have shut the rival out, established lovely attractive kitchens on the roofs fitted with plenty of nice open sky-lights, and we have linked up roof and roof, and bridged the horrid streets with a lovely network of telephone wires and cables. No primitively arboreal species could imagine a nearer approach to paradise. Every night there is a procession along these cables and over the roofs; new colonies are established in every possible place. *R. rattus* [the black rat] is now once more the Common Rat in many parts of our great city. To show how quickly it works: Bankers move in to a brand-new building on Monday; on Wednesday they think they have rats. During the week-end the backs are eaten off many of the new books, and on the following Wednesday the rat-catcher takes more than sixty out of the up-to-date roof-kitchen. We are thus fast getting back to the state of affairs which existed in the seventeenth century not only in London, but in many other of the larger ports. If this goes on we shall certainly be once more in peril of plague."

It is the old story that is ever new. J. R.

A New Philosophy of Biology

Grundzüge einer allgemeinen Biologie: die Organismen als Gefüge-Getriebe, als Normen und als erlebende Subjekte. Von Prof. Dr. Richard Woltereck. Pp. xvi + 629. (Stuttgart: Ferdinand Enke, 1932.) 40 gold marks.

PROF. WOLTERECK'S ponderous volume contains, in our opinion, a work of fundamental importance which we earnestly recommend to the attention of readers of NATURE. True to the thoroughness characteristic of his countrymen, the author has examined the problem of life from all its aspects, psychological as well as physiological, and has come to far-reaching conclusions with many of which we agree. It is greatly to be desired that the book should find a translator; but when he is found we do not envy him his task: for the author has followed the custom of German philosophers and has expressed his views in a complex syntax with many dependent clauses the unravelling of which in many cases is like making out a puzzle.

Within the compass of a review of manageable length it is impossible to give a general account of the line of argument pursued in the book; all we can do is to select certain outstanding features of Prof. Woltereck's position and discuss them.

The first thing to be noted is that the author is an uncompromising vitalist. He does not believe that it is possible to explain *any* of the phenomena of life as the workings of a machine; that is, as the result of an arrangement of unlike substances or parts in fixed relations to each other. Always, he maintains, between the beginning and end of an action there intervenes the unseen regulating vital factor.

In the view of the circumstance that vitalism has been denounced as obscurantism by high scientific authority in Britain and is supposed to be confined to systematists and morphologists, it may be interesting to notice that Woltereck is the third great German biologist to pass from materialism to vitalism; and according to what he says in his preface it required twenty years for him to make the passage. The first biologist to pass over was Driesch; the second Uexküll, and none of the three could be described as either a systematist or a morphologist. Driesch laid the foundation of the great science of experimental embryology; the core of his work remains unshaken until the present time and none of his arguments has been successfully answered. Uexküll in his epoch-making work on Echinoderm physiology anticipated by twenty years discoveries in muscle physiology, which when they were rediscovered by human physiologists, excited the greatest interest and astonishment.

Woltereck's great scientific achievements may not be so familiar to non-zoological biologists, and therefore a brief notice of them may be inserted here. He worked out in minute detail the embryology of the primitive Annelid *Polygordius* and laid the foundation for our understanding of the meaning of the trochophore larva. He showed that this larva has at the beginning of its development a radial structure which is fundamentally that of a primitive Ctenophore, and he gave a suggestive theory as to the manner in which this Ctenophore ultimately became a worm. His work is comparable in importance with Sedgwick's description of the embryology of *Peripatus*. Of late years Woltereck has devoted his attention to the experimental modification of development and has chosen for his subject the minute crustaceans belonging to the group Cladocera (*Daphnia* and its allies) and he has proved up to the hilt the inheritability of induced modifications—in plain language, acquired characters. Some of his experiments, such as transplanting a German strain to Lake Nemi in Italy, have lasted twenty years.

The fact is that, when we think the matter out, vitalism is not obscurantism but commonsense. For as Woltereck insists, we must begin our analysis not with matter but with experience, because matter is only a name for 'our' interpretation of part of this experience which is presented to 'us'. In a word, there is no such thing as experience *in vacuo*; it is always the experience of some one; and this knowledge of our own life, which is immediate and certain, is the safest guide to the real nature of the life of other beings. So Woltereck is driven to the conclusion that there is something, however dim and rudimentary, analogous to feeling even in plants.

Woltereck endeavours to show that in its final analysis life can be reduced to a series of 'impulses' or strivings. These impulses may be 'answers' to something in the environment, or they may be autogenous, the latter term referring especially to the successive impulses which carry development from the egg to the adult form. But all these 'impulses' show the same fundamental character. They are directed to the

attainment of an 'end', and if prevented from reaching this end in one way they will seek it in another. This is seen equally when a Stentor seeks to avoid an irritating shower of chalk particles by sweeping them away by ciliary action, then by bending its head to one side, and finally by swimming away, as by a distorted egg constructing the future embryo out of totally different materials from what it would have used if left undisturbed.

When he comes to consider the question of racial evolution, Woltereck is scathing in his references to 'natural selection'. He says that the doctrine that the orderly growth of one species into another can be explained by 'chance' variations, has produced some of the most curious mental aberrations in the history of psychology. On the subject of 'mutations' he takes up what seems to us a perfectly sound position: he says that ninety per cent of them are pathological (we should have said a hundred per cent), that they deal with 'additive' characters which do not affect the real constitution of the organism and have therefore had nothing to do with racial change. He is inclined, we think, to take the crude conceptions of the Morgan school as to the 'genes' being in the chromosomes too seriously, even admitting their identification with the 'chromioles' seen in stained preparations, but he insists that the hereditary substance is not made up of genes (therein the late Dr. Bateson would have agreed with him): these he regards, like hormones, as secretions of this substance which have certain definite effects.

When Woltereck considers the Lamarckian theory of evolution, it is clear that he does not really understand what that theory is, and that many of his difficulties would have disappeared if he had grasped its meaning. He refers to the theory as the "direct influence of the environment" and asks if it be a real explanation of evolution why in a uniform environment there should be such a varied fauna. His own experiments on the inheritance of induced modifications he discounts, because the altered progeny when returned to the original conditions, slowly through a considerable number of generations, reverted to the typical form.

Now if there is one thing on which Lamarck insisted it was that the environment exercised *no direct influence on the organism whatever*: it caused, however, the animal to adopt new habits; and it was the exercise of these habits which modified structure. Woltereck mentions the case of the perch-like fish, the *Cichlidæ*, in Lake Tanganyika, all of which seem to be modifications of one or at most two ancestral species introduced into the lake but which now are divisible into many species. This case has been studied in detail by Dr. Tate Regan, and he has shown that the cause of the differentiation of these species is the different kinds of food which they have selected and the various ways in which they seek it; in a word, their habits. Mr. Hinton, keeper of mammals in the Natural History Museum, has mentioned a case where three different species of rodent with different colours of fur inhabit the same burrow in the arid parts of Syria. Here is a case which seems to prove that colour is independent of environment until it is discovered that one species is diurnal, one nocturnal, and the third crepuscular, in its habits.

Coming now to the reversion of induced modifications to type when replaced in the typical environment, which Woltereck (and also Przibram) considers as a bar to regarding them as the real producers of new species, two things are forgotten; namely, (1) that this is what was to be expected, (2) time. For if change in environment will modify organisms in one direction a change back again will tend to modify them in the opposite direction; but the longer a habit has been exercised and the more deeply it has affected structure, the more it will resist modification; and the changes in habit embodied in specific distinctions are very old things. Lamarck with prophetic insight insisted on the importance of time in his theory of evolution, asserting that only habits which had persisted *a long time* had an effect on structure. It is significant, as Woltereck informs us, that at the Congress on Hereditary Science, held in Germany in 1929, practically all the palæontologists adopted a Lamarckian position.

Woltereck does himself less than justice when he suggests that Lamarckian evolution may have played a part in the formation of species within a phylum, but that for the start of a new phylum a sudden beginning—a new 'mutation'—must be assumed. For his own work on the trochophore has enabled us to connect together such diverse groups as the Annelida, the Mollusca, the Rotifera and the Polyzoa, and to show that they are all descendants of the same ancestral group and to discover the changes in *habits* which led to the original separation of two different phyla. Such an event was at first slight in itself but led in the course of ages to such momentous consequences,

and such a fundamental cleavage in structure, that even first-rate biologists like Woltereck are deluded into supposing that the cleavage must have commenced with a miracle.

To the invocation of 'mutations' as explanations of radical differences, we are fundamentally opposed because this method of dealing with difficulties seems to us mere indolence of thought. Does an embryologist discover in some member of a vertebrate family a very aberrant type of development? It is not clear to him how it originated; therefore it must be due to a 'mutation'. Does a botanist discover on the top of a mountain an aberrant species of a genus other species of which flourish on the lower slopes? What is easier than to explain the new species as due to a 'local mutation'? In fact, the mutation is used exactly as the 'joker' is employed in the games of euchre and coon-can to supply the place of any card needed to complete the trick. Subsequent research has shown that the supposed 'local mutation' is found on other mountain tops and is in fact the remains of a northern species finding its last retreat on the cooler heights, and we have no doubt that in time a satisfying explanation will be found for the aberrant type of development.

The vitalistic views of Woltereck will certainly awaken the most determined opposition on the part of many biologists, but in our opinion these views constitute a valuable contribution to biological science. Opponents of vitalism fall into two groups. There are first out-and-out materialists, or, as it is now the fashion to call them, 'mechanists', who believe that matter and energy are the sole realities in the universe. To discuss the difficulties of this position would lead us too far; it is sufficient to notice that it was emphatically repudiated, at any rate in his later days, by T. H. Huxley. But there is a second and more moderate group which, whilst admitting that there may be a non-mechanical factor in all living things, think that the only scientific method of approach is to treat them *as if* they were mere masses of carbon compounds and to endeavour to explain their activities as outcomes of their chemical composition. The legitimacy of this view is beyond question; its value will be determined by its success in practice, but to our mind it is like attempting to solve an equation whilst completely disregarding one of the unknowns. In this way at best only a partial solution could be hoped for, and it is significant that so far along this road no complete solution of even the simplest living phenomenon has been attained. In fact, as Prof. J. S. Haldane has remarked, the failure has been colossal. When we approach the problem of development even the faintest semblance of an explanation on mechanistic lines becomes impossible, and it was this circumstance that originally converted Driesch to vitalism. If instead of dismissing the unknown factor, as a mysterious entelechy, which was the procedure adopted by Driesch, we endeavour with Woltereck to come to some understanding of the laws of its action, a distinct advance will have been attained.

Let us conclude by giving one example of this latter procedure, admirably described by Woltereck. A young Radiolarian, he remarks, is a mere sphere of clear protoplasm containing a central nucleus. From its periphery stream out delicate interlacing strands of almost fluid protoplasm. As the Protozoon grows older, delicate needles of silica, each adorned with characteristic outgrowths, sprout out from it, until in the end a series of concentric baskets of silica may result. The shape, branching and arrangement of these needles is a fixed specific character. They are laid down, however, by fluid strands of protoplasm. To what is this fixity of pattern due? Certainly not to the arrangement of molecules in the protoplasm, for these are constantly rolling over each other like the molecules of any other fluid. Woltereck, like some other leading German biologists, is driven to the assumption of a 'biological field', which like a magnetic field compels particles entering it to arrange themselves in certain definite patterns. The biological field itself is due to an influence radiating from a centre, presumably the nucleus, but it cannot be explained on mechanistic lines. In Woltereck's opinion, the production of these fields is the mode by which the vitalistic activity present in the ovum ultimately builds up the adult body. To sum up, vitalism regards an organism primarily not as a substance but as an activity; and the activity to a considerable extent controls the constitution of the substance.

As we finish this review we are painfully conscious of its inadequacy and of the numerous profound thoughts in Woltereck's book which it has been impossible to mention. To do justice to these would require a treatise rather than a review. If what we have written induces readers of NATURE to become acquainted with Woltereck's book themselves we shall be satisfied.

E. W. MACBRIDE.

Algebraic Plane Curves

A Treatise on Algebraic Plane Curves. By Prof. J. L. Coolidge. Pp. xxiv + 513. (Oxford: Clarendon Press; London: Oxford University Press, 1931.) 30*s*. net.

THERE was a time, not so very long ago, when the words geometry and mathematics were almost synonymous. To-day the pure mathematicians, in every country except one, are nearly always analysts; even the minority who still call themselves geometers generally occupy themselves with some of the differential aspects, avoiding diagrams and filling their pages with symbols, as if they felt that their continued existence depended upon conforming as much as possible to the fashions prescribed by the all-powerful analysts. But we need not despair; rare animals have been saved from extinction by measures of protection taken just in time, and now Prof. J. L. Coolidge comes to the assistance of algebraic geometers with a book written in the spirit of and dedicated to the geometers of Italy, the only land in which they still flourish.

There is a great need for such a book, for Salmon's great work has long been obsolete, belonging to an age that knew nothing of Nöther's fundamental theorem and was content with a naïve process of counting constants. Recent English books give a good account of curves of the third and fourth order or other special topics, but they have very little about general theorems. Perhaps the best account of general methods is given in Severi-Löffler's "Vorlesungen über algebraische Geometrie", but this omits many important parts of the theory, and Severi's "Geometria algebraica" has as yet reached only its first volume.

Prof. Coolidge's treatment is very extensive, so far as the general theory is concerned. His only important omissions are just those special topics which are readily accessible elsewhere. It is useless to look here for the properties of the bitangents of a quartic, but there is something about curves classified by their genus, such as rational curves, elliptic curves, and so forth. The emphasis is on Nöther's theorem (now the foundation of the subject), Plücker's equations, Cremona transformations, and the theory of correspondences (treated in a special case by Chasles, discovered intuitively by Cayley, and first proved by Brill). A useful feature is the inclusion of a brief treatment of invariants, including the Aronhold symbolic notation, which is used later in dealing with apolarity. The notation of the tensor calculus is also used, though not very often.

In studying linear series of point-groups on a curve, much use is made of Abelian integrals, the leading properties of which are briefly explained. At this point the analysts will chuckle. There seems no reason why algebraic geometers should not be able to work out all about algebraic correspondences by strictly algebraic methods, but the melancholy fact is that they cannot; and up to the present they continue to upset the already unfavourable balance of trade between geometry and analysis by importing devices foreign to their subject, such as Abelian integrals.

There are a few minor points upon which the book seems open to criticism. The frequent avoidance of homogeneous co-ordinates by using unity as a variable and differentiating with respect to it is admitted to be "rather bizarre" (p. 7) and a "curious trick" (p. 12). The definition of circular points at infinity (p. 14) appears artificial, and moreover contains an unfortunate misprint which may puzzle a beginner. The treatment of asymptotes could have been improved. But on the whole, the book will be of great use to students in providing a source, perhaps the only accessible source, of a subject which, though at present unfashionable, must remain one of the "invariants, matters of abiding interest and importance, which deserve to be always held in honour".

H. T. H. PIAGGIO.

Ethnology of Mysore

The Mysore Tribes and Castes. By the late H. V. Nanjundayya and Rao Bahadur L. K. Ananthakrishna Iyer. Vol. 4: K–V. Pp. x + 677 + 68 plates. (Published under the auspices of the Mysore University.) (Bangalore: Mysore Government Press, 1932.) 12.8 rupees; 20*s*.

MR. ANANTHAKRISHNA IYER and his late colleague have now supplied us with the third of the four volumes in which the castes and tribes of Mysore are described on the lines laid down in 1902 for the Ethnographic Survey of India. The first volume, which is to be issued last and will summarise the contents of the other three, will be awaited with special interest.

The present volume presents two specially noteworthy features. It contains an account of the Lingāyats, that un-Brahmanic Hindu community numbering many millions which presents the remarkable aspect of a reform movement starting on

a non-caste basis and gradually succumbing to the caste prejudices of the later converts. Panchamsalis with the full eightfold sacraments, non-Panchamsalis with the same privileges, and the lower orders without these rites roughly represent the Virashaiva community in its present-day form.

The compiler of this volume has drawn copiously on an article in Hastings' "Dictionary of Religion and Ethics" for his materials. The value of the account would have been greatly increased by some mention of the sub-divisions of Mysore Lingāyats on the lines of those given in "Tribes and Castes of Bombay". A similar omission may be noted from the article on Musalmans. The author of this work is to be congratulated on the new and valuable materials given in the articles on Kurubas, Madigas, Morasu Okkalu, Nayinda, Sadaru, Oddars, and Uppars, which bring to notice the important exogamous sections known as *bedagus*, which are equivalent to the well-known Marātha *devaks*. Some novel and suggestive trees, plants, and animals will be found in these lists, which are the real indication of the origin of such social elements, however these may be hidden in popular tradition.

The compiler of the work, who has quoted somewhat lavishly from published accounts of Marāthas, might have added some original matter describing the Marātha *devaks* found in Mysore, as a contribution to the subject. The article on Kurubas is perhaps one of the most informative in the volume. There seems to be a close parallel, suggesting more than mere resemblance, between the Kāla Kunbi (or Kare Vakkal) of the Bombay Presidency and these Kurubas of Mysore. The costume of the women is strikingly similar, and there are many other points of contact.

A number of excellent illustrations exhibit typical specimens of the types described in the work. Unfortunately, one of the best, the Sanyāsis (p. 571), has suffered much in reproduction.

The criticism that has so frequently to be passed on works of this nature produced in India, and which has been applied to the two previous volumes of this series, is a want of care in revising proofs, resulting in misspellings and varying forms of the same word which might easily be avoided and do much to disfigure the pages. In spite of six errata, an incorrect version of the name of the author of "Tribes and Castes of Bombay" has remained uncorrected (p. 476). We find such curious slips as Myroba jam (p. 277) for the well-known myrabolam or *hirda*, and *manganefera* for the *mangifera* or mango. Okkalu is spelt in four different ways.

The assistance of well-known works on Indian trees and shrubs might well have been invoked to enable the writer to give the botanical equivalents of the numerous terms mentioned in the vernacular for the totem articles, which are of great importance. In India, with its wealth of languages, the work of comparison of these useful lists is only possible if the common botanical equivalent is shown against the local designation. The *ari* or *benni*, for example, is not readily identifiable with the *apta* unless it is shown as *Bauhinia racemosa*. Similarly, we do not connect the *muttaga* with the *palas* unless we are told that it is the *Butea frondosa*. The *nagare* and *kare* lack the revealing *Calophyllum tomentosum* and *Diospyros assinilis* which would expose their identity to the general reader.

With these remarks, relating to small defects that could readily have been avoided, this notice may be brought suitably to an end by acknowledging very cordially the debt that students of ethnology owe to the University of Mysore and Rao Bahadur Ananthakrishna Iyer for the three important volumes of which the present is the conclusion. Such works pave the way to a further and much-needed undertaking. This should deal, on the basis of published materials, with the tribes and castes of India taken as a whole, rising above the limitations inseparable from the artificial restrictions of provincial and State boundaries. It is to be hoped that such a work may be put in hand before it is too late. R. E. E.

Short Reviews

(1) *Heimskringla: or the Lives of the Norse Kings.* By Snorre Sturlason. Edited with Notes by Erling Monsen and translated into English with the assistance of A. H. Smith. Pp. xxxviii + 770 + 12 plates. (Cambridge: W. Heffer and Sons, Ltd., 1932.) 18*s*. net.

(2) *The Culture of the Teutons.* By Prof. Vilhelm Grönbech. (Published at the expense of the Rask-Ørsted Fund.) Translated into English from "Vor Folkeæt i Oldtiden", I–IV., Copenhagen, 1909–12, by W. Worster. Vol. 1. Pp. v + 382. Vol. 2. Pp. 340 + 142. (London: Oxford University Press; Copenhagen: Jespersen og Pios Forlag, 1932.) 30*s*. net.

(1) "HEIMSKRINGLA", the history of the Norse kings compiled by Snorre Sturlason, of Iceland, probably only a few years before his death in 1241, is a historical document of the first importance. Not only does it give a vivid picture of the culture and society of early Scandinavia, but also it has value as a record of the racial movement from the north which harried medieval Europe, written from the point of view of the raiders themselves. Moreover, it covers the voyages of the Norsemen

to Greenland and the discovery of Winland, that is, some part of the American mainland, although the chapters in the narrative which deal with the voyage of Leif Ericson have been held under suspicion as an interpolation. With this judgment, however, the present editor does not agree. The Ynglinga Saga dealing with events up to the birth of Halvdan the Black in 820, where Snorre's more detailed history of the Norse kings begins, gives a view of paganism and the early history of Scandinavia which is distinctly individual among early chronicles in its attitude to such matters.

Students will be grateful for this translation, in which style and language are happily adapted to the subject-matter. The editor has provided an introduction which deals with the life and writings of the author, the manuscripts, the Norse kings and the Nordic races, the Danes in England, and cognate matters. He also annotates the text.

(2) "The Culture of the Teutons", a translation of a work by the professor of the history of religion in the University of Copenhagen, might almost be termed a psychological handbook to the early literature of Scandinavia and Iceland. Although it refers to Anglo-Saxon, Burgundian and Lombard, as well as the Germanic tribes, it is concerned mainly with the Norsemen. Institutions are analysed in detail on the basis of the indications afforded by the literature, but with reference to their psychological content rather than their form. In other words, the author aims at a reconstruction of Norse society from the point of view of the Norsemen themselves. As he points out, the reader of the epics and sagas enters upon a new world which is open to misinterpretation if regarded from the modern point of view. The book is a valuable contribution to a study of many obscurities, and a translation into English is welcome.

Probleme der Wasserwellen. Von Dr. H. Thorade. (Probleme der kosmischen Physik, herausgegeben von Prof. Dr. Christian Jensen und Prof. Dr. Arnold Schwassmann, Band 13–14.) Pp. viii + 219 + 11 Tafeln. (Hamburg: Henri Grand, 1931.) 20 gold marks.

ALTHOUGH it is usual, in expounding the elements of wave motion, to refer to water waves as examples, there is probably far less known of the behaviour of real waves on water than there is of the behaviour of waves of light or sound. The study of both the experimental and theoretical aspect of, for example, ocean waves, or of the generation of waves by wind, encounters formidable difficulties, and the complexities of tidal problems are well known. From the time of Scott Russell to the present day labours of, among others, Proudman and Havelock, the subject of water waves has received substantial contributions from British men of science, and there will probably be many British readers who will welcome Dr. Thorade's book, which appears as Nos. 13 and 14 of the series "Probleme der Kosmischen Physik", edited by Profs. Christian Jensen and Arnold Schwassmann.

While the book outlines the methods and results of the chief mathematical investigations, including the most recent, it is free from detailed mathematical expositions, for which the reader is referred to the standard textbooks, such as that of Lamb, and to the original papers, of which there is an extensive bibliography. It gives a very good and clear account of tidal waves and surface waves in their many aspects, and a discussion of what is known of their mechanism, with special reference to outstanding problems. Particular mention must be made of the many diagrams, excellent alike in planning and execution, which help considerably with the discussion. There are, in addition, five beautiful photographs reproduced as plates. Many physicists with no specialised knowledge of water waves will find the volume of great interest.

Nature Photography. By Oliver G. Pike. With Chapters on Big-game Photography, by Major Radclyffe Dugmore; Marine Photography and Low-power Microscopy, by F. Martin-Duncan; Photography of Plant Life, by E. J. Bedford. Pp. xii + 196 + 53 plates. (London: Chapman and Hall, Ltd., 1931.) 12*s*. 6*d*. net.

WITH the coming of the cinematograph and the large aperture lens, and with the great improvement in the quality of telephoto lenses, Nature photography has made such strides that excellent photographs of pre-War days seem childish beside the modern product. There are many who would follow the new technique did they know how, and to them the revelations in this book will be welcome and helpful. There are hints on cameras and lenses, on the construction of 'hides' and methods of approach, on cinematograph work, special chapters by experts on big-game, marine and plant photography and on low-power microscopy, accompanied by illustrations of the art and an anecdotal narrative that makes the book good reading for the field-naturalist as well as for the Nature photographer proper.

Flotation Plant Practice. By Philip Rabone. Pp. xi + 141. (London: Mining Publications, Ltd., 1932.) 10*s*. 6*d*.

MANY physicists interested in the application of physics to industry will welcome the appearance of a work dealing with flotation practice which is not so detailed as to be burdensome, and is yet full enough to come down to such practical details as costings. Mr. Rabone's book deals, in less than 150 pages, with such topics as crushing; grinding; flotation reagents, machines and methods; and concentrate and tailing disposals. He has found space to devote a few pages to the theory of the method, and although he remarks that some may think that his treatment of the theory of flotation "is more extended than the scope of the book warrants", this section could certainly be expanded with advantage.

The book is compact in size, well produced and illustrated, and may be recommended. A. F.

The Internal Photoelectric Effect in Crystals

By A. H. WILSON, Cavendish Laboratory, Cambridge

THE extensive work of Gudden, Pohl and others has to a certain extent clarified the behaviour of insulating crystals which become electrical conductors under the influence of light. In these substances the photo-conductivity is entirely electronic, and we leave out of consideration electrolytic processes in which massive ions transport the current. Crystals can in the main be divided into two groups—idiochromatic crystals which are photosensitive in the pure state, and allochromatic crystals which only become photosensitive after being treated with X-rays, or which owe their sensitiveness to the presence of impurities. It has so far proved impossible to correlate these complicated photo-effects with the theory of the solid state, but in view of the recent advances in the theory of poor conductors and of the influence of impurities on conductivity,[1] it seems worth while to see if any unification is now possible.

If we examine the possible types of photo-effect which can take place in what we believe to be a fairly correct model of an insulator, we find that we are able to explain a large part of the phenomenon known as the primary photo-electric current, which is that part of the current which is proportional to the intensity of the light. The explanation offered here is similar in many respects to the explanations put forward during the past decade by Gudden and Pohl, and may be considered as a justification of their main hypotheses. In what follows, the theoretical principles which govern the photo-conductivity will be outlined only, no attempt being made to discuss the subsidiary phenomena. A good account of the experimental results will be found in a recent article by F. C. Nix.[2]

It is now well known that the energy spectrum of an electron moving in a perfect lattice splits up into bands of allowed and disallowed energies, and if there are just sufficient electrons present to fill up one of the allowed bands, there can be no conductivity at absolute zero temperature. Further, if an electron is placed by any process in an unoccupied band, it becomes a 'free electron', and again, if there are not quite enough electrons present to occupy a band fully, then the resulting 'holes' are free to move through the crystal, and behave like free electrons with positive charge. In an insulator in the pure state, there are just sufficient electrons present to fill up one of the bands, and any conductivity is due to the presence of impurities, or has been produced artificially by electron bombardment or by the action of light. We consider as a typical allochromatic insulator sodium chloride, and for simplicity restrict ourselves to a one-dimensional lattice of n sodium atoms and n chlorine atoms arranged alternately. We further idealise the problem by leaving out of account all the electrons except one of every atom, and we therefore have $2n$ electrons to deal with. Since the sodium chloride crystal is an ionic one, the highest occupied band belongs to the chlorine atoms, and the motion of an electron in this band represents an electron jumping from one chlorine to another. This 'chlorine band' contains n energy levels, equal to the number of chlorine atoms present, and these energy levels will just accommodate the $2n$ electrons, since according to Pauli's principle not more than two electrons can ever occupy the same energy level.

When a quantum of short wave light is absorbed to sensitise the crystal, its effect is to transfer an electron from a chlorine to a sodium atom. In this state the crystal is not conducting, and so

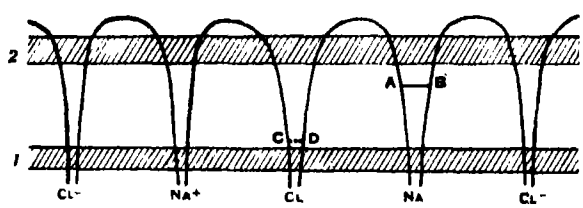

FIG. 1.

we must assume that the electron has not been excited into a band of the crystal but into a discrete energy level. The correct way of describing the crystal when it is in this sensitised state is to say that it is built up of $(n - 1)$ positive sodium ions and $(n - 1)$ negative chlorine ions in which are imbedded two impurities, a neutral sodium and a neutral chlorine. The energy levels of this system are illustrated in Fig. 1. The potential energy of an electron is drawn, and the shaded band 1 represents the chlorine band which is fully occupied, while the band 2 represents the lowest unoccupied band. Although the neutral chlorine and sodium are drawn as neighbours, it is not implied that this is necessarily so in an actual crystal.

The band 1 has $(n - 1)$ energy levels, and these will just accommodate the $2(n - 1)$ electrons belonging to the ions. The neutral sodium and chlorine have the remaining two electrons in discrete states. The energy level of the electron on the sodium is represented by AB, and the energy level of the 'hole' caused by the removal of the electron from the chlorine ion is represented by CD. The whole crystal is non-conducting provided the energy level AB lies below the band 2, and provided CD lies above 1. In thinking of these bands, it is essential to remember that they are energy bands, and not localised in space, so

that we have drawn band 1 crossing both the sodiums and the chlorines, although it is a chlorine band. Only the discrete states can be thought of as belonging to one particular atom. The crystal in this excited state cannot be stable, but since in some cases, of which rock salt is an example, it can exist for years, it must be in a metastable state. Since any electron from the band 1 of the original crystal may be excited into a state such as AB, the absorption of light is continuous over a range of frequencies corresponding to the width of the band 1. The continuous absorption is therefore due to the initial state belonging to a continuum and the final state being a discrete one, whereas in atoms and molecules it is the final state which belongs to a continuum. In rock salt the absorption which sensitises the crystal takes place in the ultra-violet and X-ray regions, though in the silver halides the absorption extends into the visible.

If the crystal is now placed in an electric field and illuminated with light of such a wave-length that the electron in the state AB is ejected into the band 2, a current will be observed, and this constitutes what is known as the primary negative current. A new absorption band has therefore been introduced into the crystal at a wave-length which is usually considerably longer than that of the light required to sensitise the crystal. In rock salt this absorption takes place in the yellow. After the negative current has ceased to flow, we are left with a lattice in which there are n sodium ions, $(n - 1)$ chlorine ions and one neutral chlorine atom, among which are to be divided the $(2n - 1)$ electrons. Of these electrons, $2(n - 1)$ are just sufficient to fill the band belonging to the chlorine ions, and the remaining one is attached to the chlorine atom in a discrete state, so that the crystal is once more non-conducting.

This is not the only possible state of the system. Another possible configuration is that in which there are n positive sodium ions, and n exactly similar chlorine ions with $(2n - 1)$ electrons distributed among them. In this configuration the crystal would be conducting, the conductivity being caused by the vacancy in the shell of electrons forming the chlorine band, and this 'hole' behaves like a positive electron. In rock salt this state of the crystal has greater energy than that in which one of the chlorines is neutral, and we may represent the state of affairs schematically by saying that the neutral chlorine atom has a vacant energy level CD, which can take up an electron from the band 1 if an amount of energy is supplied represented by the difference in energy between CD and the band 2. This energy may be supplied by illumination with infra-red light, or by heating, in which case the energy is supplied by the lattice vibrations.

Provided the temperature is low enough, it is possible to keep the crystal in the non-conducting state for a long time, and to let it pass over slowly into the conducting state, thereby separating out the positive current from the negative current, which appears immediately the crystal is illuminated. Gudden and Pohl ascribe the possibility of this separation to the sluggishness with which the 'holes' move through the crystal. According to the present theory, the 'holes' in a band can move through the lattice as quickly or nearly as quickly as the free electrons, and the sluggishness of the positive current is due to the slowness of the change from a non-conducting lattice with a neutral chlorine imbedded in negative chlorines to a conducting lattice in which all the chlorines are on the same footing.

It might quite well happen that the state AB does not lie below the band 2, but actually in it. In this case AB can no longer be thought of as being discrete, but belongs to the band 2. The electron on being removed from band 1 immediately becomes a free electron, which is the characteristic of an idiochromatic crystal, a typical example being diamond. In diamond the configuration of the crystal with lowest energy, after an electron has been ejected, seems to be made up of a positively charged carbon atom imbedded in neutral carbons, and the 'hole' which is left therefore corresponds to a discrete state of exactly the same nature as CD in Fig. 1. So for diamond, as for rock salt, the negative and the positive currents can be separated. In order to bring the diamond into a state in which a positive current can flow, it is necessary to supply energy in the form of infra-red light or heat, and then the crystal passes over into the state in which all the carbon atoms are on the same footing, and in which there are not quite enough electrons to fill up a band.

A further possibility is that, when an electron is ejected from the band 1, the state of lowest energy is that in which all the atoms are on the same footing. In this case the positive and negative currents must flow simultaneously, and there would be no possibility of separating them. This case would be represented by the level CD lying below the top of the band 1, a state of affairs which seems to be realised for sulphur. The 'hole' cannot then be considered as being attached to any particular atom. However, it should be borne in mind that the conducting state may merely have lower *free energy* than the non-conducting state, and that at very low temperatures sulphur might behave in the same way as diamond.

We may conclude from the above discussion that the theory reproduces quite naturally many of the most striking features of the internal photo-effect, and that there is no essential difference between idio- and allochromatic crystals, or between those in which the negative and positive currents can be separated and those in which they cannot. The criterion for distinguishing the various cases is whether an electron in a pure insulator goes into a discrete state such as AB on absorbing light or into a band such as 2, and whether the resulting 'hole' corresponds to a discrete state such as CD or whether the 'hole' lies in the band 1.

It must, however, be admitted that there are still many puzzling features of the primary current. In allochromatic crystals the photoelectric response and the absorption of light correspond very well, but in idiochromatic crystals the photoelectric response has a maximum near the long wave edge of the absorption band and falls off very rapidly in the interior of the band where the absorption is large. It therefore seems that, when the absorption is large, there is no conductivity (the absorption of the light which produces the photo-effect in allochromatic crystals is always small). This seems to mean that, when many electrons are excited in say diamond, they go into discrete states and not into a band. One can see vaguely that, when many atoms have electrons excited, the original classification of states into bands, based on the properties of a perfect lattice, is likely to break down, and to be replaced by a classification based on the properties of the individual atoms, but such an explanation cannot be considered as satisfactory. This and many other problems must await further developments of the theory before they can be tackled successfully.

Hormones and Evolution

By J. T. CUNNINGHAM

ACCORDING to the most advanced results of genetical research, evolution is to be investigated by statistical and mathematical methods. The researches and conclusions of the geneticists are governed by the conceptions of species and divergence. It is obvious that the production of the many varieties of rabbits, dogs, and other mammals, and of birds, under domestication, to say nothing of plants, is an example of evolution; and it may possibly be to a great degree, if not entirely, explained by random mutation and survival. But the geneticists ignore many other phenomena which are equally or more important than the origin of varieties or species, especially the phenomena of adaptation. They regard survival as equivalent to selection, but that term as used by them means usually indirect selection. The survival is attributed to greater viability or fecundity, not to the utility of diagnostic characters. Genetics include extraordinary discoveries concerning sex-linkage, but almost nothing about sex-limited characters, which are known to be inherited by both sexes but developed exclusively or to a greater degree in one.

The doctrine of genes appears to be satisfactory in relation to variation and the origin of varieties and species, but it fails to explain adaptive evolution. When we consider the origin of terrestrial from aquatic vertebrates, the various adaptations of limbs to flight in birds, mammals, and some extinct reptiles, the reversed adaptation of air-breathing vertebrates to aquatic life, and many other obvious and direct adaptations, it is a truism to say that their development in the individual depends on genes in the nuclei of ova and sperms, but it has not yet been shown that they can be explained by any random mutation of the genes. The difficulty is still greater when we consider metamorphosis. It may be admitted that the metamorphosis of the flat-fish is the result of its genetic constitution, although we do not know precisely how the genes produce the hereditary characters in development. But here we have a change in important structural characters from a symmetrical phase with the median plane vertical to an asymmetrical phase with the median plane horizontal, a change taking place gradually in post-embryonic life and corresponding with the change in the relation of the fish to the direction of light and gravity.

We are asked to believe that this co-relation of structural development with external forces is not due to any effect produced by those forces, but to random mutations in the genes which were independent of the external forces, and the survival of those mutations which had the complex co-relation which we see. If we used the mathematical symbols of which the modern geneticist is so fond, how should we express the probability of the production of such an adaptation by random mutation and selection? The gene theory in this case must assume that every conceivable mutation may occur, including those which determine the change from symmetry to asymmetry in the individual, and that sooner or later each is bound to occur, so that selection is omnipotent. But there is no evidence of the occurrence under experiment or observation of the occurrence, uninfluenced by external conditions, of anything like the distortion of the skull which causes the change in the position of the eyes in the flat-fish, and leaves the symmetry of the anterior and posterior regions of the skull unaffected.

The problem of evolution can be attacked from either end of the ontogeny, from the genes to the development of the characters, or from the characters back through development to the genes. Adaptation does not consist merely in the possession of characters which are supposed to be useful or beautiful like the spots on the back of a beetle or the ocelli in a peacock's tail, but also of the functions of organs and their relation to the organism's

mode of life. One of the most curious phenomena to be explained is the influence of internal secretions or hormones on development and function. In the case of the antlers of stags the exclusive development in the male is due to the hormone secreted by the testes. This is an example of the sex-limitation of organs only indirectly related to the reproductive function. In the female mammal the functional cycles of the accessory reproductive organs which form such a remarkable difference in them from the birds and reptiles, are also controlled by hormones. In 1908 I put forward the theory that the origin of the influence of the testicular hormone on characters limited to the male could be explained by the inheritance of the effects of external stimulation. In the case of the stag, the development of the antlers according to this theory was due to the mechanical stimulation of the periosteum of the frontal bone by blows and friction in the fighting between rival stags, and both this development and its association with the presence of the testicular hormone were transmitted to the reproductive cells or gametes, in modern terminology to the genes. No theory of random mutation originating in the genes affords any reason for the evolution of this peculiar association of the sex-limited character with the internal secretion of the testis.

With regard to the female mammal, I suggested that the origin of the reproductive cycle and its hormonic control could be traced to the retention of the ovum in the oviduct during its development, and the stimulation of the uterine walls by the nutrition and growth of the embryo and by the placenta. Similarly the mammary glands on this theory were primarily due to the mechanical stimulation of the skin by the sucking of the young which led to the hypertrophy of dermal glands. Afterwards it was discovered that the anterior lobe of the pituitary produces one or more hormones which influence œstrus and the formation of corpora lutea in the ovary. Cases of precocious sexual maturity in the human subject have been found associated with tumours of the adrenal body. In order to cover such facts, I extended my theory to all the endocrine organs, postulating that the hypertrophies caused by the developing fœtus were inherited not merely in association with the hormone of the ovary or ovarian follicles, but also in association with the normal hormone complex, so that excess or defect in any one of the more active of these organs caused abnormalities in the sexual cycle: injection of pituitrin, for example, causing formation of corpora lutea, the modification in mammals of the ovarian follicles from which ova have been discharged.

Apparently the secretion of the pituitary is the most active of the hormones not derived from the reproductive system itself, and it has the most marked influence on the ovary in the mammal. But it has no such effect on frogs or oviparous reptiles or birds, although it produces the same secretion in these animals. If the formation of corpora lutea were the effect of gestation, this result at the beginning of the evolution of gestation would occur in association with the presence of pituitrin in the body. If the acquired character were transmitted to the genes it would still be in association with pituitrin, so that injection of the latter would cause the formation of corpora lutea when there was no ovum or fœtus in the uterus. The action of a hormone on this theory suggests an analogy with that of the associated stimulus in a 'conditioned reflex'.

The physiologist finds that the secretion of the pituitary affects the phases of the reproductive cycle, and concludes that the gland goes through a cycle which causes the reproductive cycle. But that is no explanation; the question still remains what causes the pituitary to pass through such a cycle in mammals and other viviparous vertebrates and not in oviparous forms. On the theory that the external stimulation, that is, the presence of the developing ova in the oviduct, was the original cause and that the effects of this were inherited in association with the hormone plexus, we have an explanation, whereas genetics and physiology give none. This extension to the whole hormone complex of my theory of the association of secondary sexual characters and the female sexual cycle in mammals with the hormones of the reproductive organs was communicated to the Second International Congress for Sex Research, held in London in 1930.

Having given so much attention to the subject, I was very much interested in the letter by Prof. Landsborough Thomson on the evolution of hormones published in NATURE of October 8. This is the first discussion by any other biologist than myself, which has come to my notice, of the evolution of the relation between hormones and development, especially with reference to sex-limited characters and accessory reproductive organs. Prof. Thomson naturally uses technical physiological terms which are unfamiliar to other biologists, such as 'integrative mechanism' for the action of one part on another by which the functions of the organs are co-ordinated. He refers to the evidence that some of the chemical linkages have been established by the evolution of a tissue responsive to a substance already present in the organism. He thus agrees with me on the point that the hormones were in existence before the responsive tissues or developments were evolved.

It is therefore not the evolution of the hormones which has to be explained, but the evolution of the response to the hormones. I hope that Prof. Thomson will consider the theoretical suggestions which I have published and agree that external stimulation (regarding the ovum and developing embryo in the oviduct or uterus as really external to the organism) affords a reason for the evolution of the special responses, while the doctrine of random mutation cannot be applied to this case because the obvious association of the new development, whether corpus

luteum, mammary gland, or antlers in the stag, with a new stimulation is inconsistent with the term random.

Prof. Thomson refers to the vestigial survival in the mammal of the substance which causes expansion of chromatophores in Amphibia and teleosts. But is not the fact rather that the pituitary remains the same while the chromatophores have disappeared in the mammal? He also refers to the discovery that the development of the crop gland in the pigeon is stimulated by a (or, the) hormone of the pituitary which also stimulates the development of the mammary glands of the guinea pig. Here is an instance in which it is evident that the conception often implied in such terms as 'the œstrus-producing hormone' is not strictly correct, that the hormone does not cause the special development of tissue but that its presence is necessary to the development of which the potentiality is present in the genetic constitution. The testis hormone is necessary to the normal development of the antler in the stag but does not produce antlers in the stallion. Usually in experimental biology the pituitary of the ox is employed for researches on vertebrates of various classes, fishes, amphibia, birds and mammals, which implies the assumption that the internal secretions of the organ are essentially similar in all these classes. My theory that the mechanical stimulation, in one case of the membrane of the bird's crop, in the other of the dermal glands of the mammal, caused hypertrophy which in course of time affected the genes within the reproductive cells in association with the hormones of the pituitary, so that the hypertrophies became hereditary, is in harmony with the facts to be explained.

The case is quite similar to that of male sex-limited characters in mammals, where the testis hormone influences the development of antlers in stags, of teeth in the boar, and of the snout in certain seals. There are different responses to the same hormone, but the different responses correspond with different external stimulations. If it be replied that there is no evidence that the effect of such stimulations on the soma can produce any change in the genes, I can only point out that the association of the external stimulation with the presence of the hormones corresponds with the associations of the hormones with genetic development, and that it is impossible to ignore the fact that the hereditary hypertrophy controlled by hormones is physiologically of the same nature as the effects of the external stimulation, and the other fact that the stimulation is not merely hypothetical and supposed to have occurred at some remote period in the past but continues at the present day.

Obituary

CANON JOHN ROSCOE

WHEN in the 'nineties of last century I had the great good fortune to make the acquaintance of my valued friend, the late Canon John Roscoe, he was settled as a missionary of the Church Missionary Society among the Baganda, the great tribe or nation which has given its name to Uganda, in Central Africa. But he had previously resided in the same capacity for some years in that part of East Africa now called Tanganyika, which was afterwards taken over by Germany and known as German East Africa. Of his life in that country and his observations of the native tribes he has given a brief account in a volume published long afterwards, "Twenty-five Years in East Africa". The account includes the notice of a curious form of human sacrifice practised by the natives which he succeeded in suppressing. He left the country at the time when the Germans took possession of it, and falling into the hands of the Arabs, who opposed the German invasion, he and his wife narrowly escaped being put to death by their captors, the messenger who brought their ransom only arriving about an hour before the time fixed for their execution.

It was not until he settled among the Baganda, however, that Roscoe began systematically to investigate and record the customs and beliefs of the natives among whom he lived. The results of his observations were first published in a series of valuable articles in the *Journal of the Anthropological Institute*, which are perhaps not wholly superseded by his systematic work on the subject, "The Baganda", which appeared some years later, in 1911. In his researches among the Baganda, he received important aid from his friend, the native prime minister of Uganda, who was not only himself versed in the lore of his people but also brought as informants from all parts of the country old men acquainted from their youth with the ancient traditions and customs which even then, at the beginning of the twentieth century, had passed or were passing out of use and even out of memory. Thus by his timely intervention, and the efficient help of his native informants, Roscoe was able to put on record a large body of information on the old life of the Baganda which otherwise would inevitably have been lost to science. His writings on the Baganda must therefore remain for all time the standard authority on that important tribe, one of the most powerful and most politically developed of all the Bantu peoples.

While his researches were in the main concen-

trated on the Baganda, Roscoe's anthropological enthusiasm, which never flagged, led him to extend his investigations to many other peoples of the Uganda Protectorate. He availed himself of his holidays to visit and examine some of them, particularly the Banyoro (or Bakitara), the Banyankole, and the Basoga, all of whose territories border on that of the Baganda, as well as other and more distant tribes, including the savage and cannibal Bagesu, on the slopes of the lofty Mount Elgon. The scientific results of these excursions he published in "The Northern Bantu", a volume replete with interesting information concerning these tribes, about which comparatively little had been previously known.

Even after Roscoe had returned to England in 1909 and was living in his quiet rural rectory at Ovington, near Thetford, in Norfolk, to which, in recognition of his eminent services to science, he had been presented by the University of Cambridge in 1912, his interest in these tribes of Central Africa remained unabated, and he longed to revisit them and push his investigations farther among them and among fresh tribes as yet untouched by European influence. Representations made on his behalf to the Government to enable him to undertake an expedition for this purpose were sympathetically received by Mr. Harcourt, then at the head of the Colonial Office, but they finally came to nothing. At last, after the War, his opportunity came, when the enlightened munificence of the late Sir Peter Mackie furnished him with the means of carrying out the wish of his heart. The funds provided by the generous donor were administered by a committee of the Royal Society, under the auspices of which Roscoe set out in 1919, and after spending about a year in the field returned in 1920. He husbanded his resources and secured complete freedom of movement by travelling alone except for the necessary bearers. It had been his wish and intention to examine the almost unknown tribes in the north-east, between Lake Rudolf and the southern border of Abyssinia, but unfortunately political complications in that region compelled him to abandon this important part of his programme, and that part of the ethnographical survey still remains undone, though I understand that there is some prospect of the blank being supplied before long by a younger investigator.

Thus restricted in the scope of his inquiries, Roscoe was obliged to retrace his steps over what to him was, in some measure, beaten ground. Still he made, in his year of absence, a wide circuit of the Protectorate, revisited his old friends the Banyankole, the Banyoro, the Bagesu, and the Basoga, and collected much additional information about them, besides breaking fresh ground among new and almost unknown tribes on the wilds of the lofty Mount Ruwenzori and elsewhere. The scientific results of his expedition were published by the Cambridge University Press in three volumes, "The Bakitara or Banyoro", "The Banyankole", and "The Bagesu". He also published a more popular account of the expedition under the title of "The Soul of Central Africa", in which descriptions of the native tribes are agreeably varied by graphic descriptions of scenery and incidents of travel—personal details which he always rigidly and rightly excluded from his strictly scientific writings.

On this expedition Roscoe devoted most time to the Banyoro or Bakitara as the most important and formerly most powerful tribe of the Protectorate after the Baganda. In his inquiries among them he received much help from the native king, who took great interest in the work and was at pains to supply Mr. Roscoe with the fullest and most authentic information. Thus my friend was enabled to do for the Banyoro what he had already done for the Baganda, to supply a great African tribe with an accurate account of its present state and past history, so far as these could be ascertained by personal observation and the most trustworthy native tradition.

As a field anthropologist, Roscoe had in his day few equals and probably no superior. He was a first-rate observer, with a keen sense of what is important and deserving of record; entirely free from theoretical bias, he always contented himself with stating in clear and simple language the results of his observations and inquiries; for him it was enough to record the facts; he did not attempt to explain them by his own or other people's theories. Still less did he fall into the trap, into which too many field anthropologists have tumbled, by comparing his African facts with facts raked together from all the ends of the earth: all such explanations and comparisons he rightly left to be elaborated by comparative anthropologists at home working in libraries on the reports of field ethnologists like himself. As one of these workers at home who have profited immensely by his researches in the field, the results of which he freely and generously communicated to me by letter and word of mouth as well as in his published writings, I desire to place on record my sense of the deep debt of gratitude under which he has laid all students of ethnology by his long and devoted labours in Central Africa. As documents of first-rate authority on the tribes of the Uganda Protectorate, his writings can never be superseded; they will remain imperishable monuments of the people and of the man.

But while his writings attest to the world the tenacity of purpose and the strength and keenness of the intellectual powers which enabled Roscoe to accomplish his great work under all the distractions of a laborious profession, and all the difficulties and hardships of long journeys performed in a tropical climate, for the most part in days when modern facilities of travel were still unknown, only his intimates knew the kindly sympathetic nature which endeared him to his friends and won the hearts of his dusky flock in Africa, as afterwards of his parishioners at home in England.

Of that, however, it is for others to speak. But

it would be wrong to conclude this brief and imperfect notice of Canon Roscoe's anthropological work without directing attention to one feature of it which added greatly to its value. All his information, I believe, was obtained directly from natives in their own language without the aid of interpreters, his own long and intimate familiarity with Bantu speech enabling him to dispense with those dangerous intermediaries in all his intercourse with the Bantu tribes who form the great bulk of the inhabitants of the Uganda Protectorate. Thus his reports of native customs and beliefs are entirely exempt from one most fruitful source of doubt, ambiguity and error which infests and tends to corrupt and falsify all testimony in passing through the medium of an interpreter, who, even if he be honest, may unconsciously pervert the purport of the communication he is charged to make through his imperfect acquaintance with one or both of the languages of which, as a go-between, he is obliged to make use. Readers of Canon Roscoe's works have, therefore, the satisfaction of knowing that the stream of his discourse flows pure and clear from native sources, unsullied by passing through the too often turbid and weedy channel of an intermediary. J. G. FRAZER.

BY the death of the Rev. John Roscoe, honorary canon of Norwich, at Ovington, Norfolk, on December 2, at seventy-one years of age, anthropological studies in Great Britain have lost a highly valued worker and the foremost authority on the beliefs and customs of former days among the Baganda and related peoples of East Africa.

John Roscoe, the son of James J. Roscoe of Liverpool, was trained as a civil engineer, but turned to mission work. After a period of training in the Church Missionary Society's college at Islington, he went out to Africa as a lay worker in the service of the Society in 1884. He was not ordained until 1893. In 1899 he became principal of the theological school at Mengo and, after holding this post for ten years, retired from mission work in 1909.

The early years of Roscoe's work as a missionary in Africa covered a stormy period in the history of Uganda, in which the intrigues of the king, Mwanga, and still more of his Lubare priests, played English and Protestants against French and Roman Catholics and Islam against both, until the establishment of a protectorate was forced on Great Britain as a virtual necessity. As the powerful king Mutesa had died only shortly before his arrival in the country, Roscoe had the advantage, inestimable for his subsequent studies, of seeing something of the working of a great African kingdom, even though in disturbed conditions, before it had been modified by European control. Further, in his studies of Baganda institutions his own first hand observation was supplemented by the help of his friend, Sir Apolo Kagwa, the native *katikiro*, or prime minister of Uganda, who not only gathered in his house for Roscoe's benefit old men from distant parts of the country, who were repositories of obsolete custom and belief, but also submitted Roscoe's material to the test of his own knowledge and critical judgment. Roscoe had taken up anthropological inquiry as a relaxation from teaching; but his early papers published in the *Journal of the Anthropological Institute* showed that he was a meticulously accurate observer, who at the same time was competent to see his facts in their broader relation. His reputation was confirmed and enhanced by his books, "The Baganda" and "The Northern Bantu".

On his return to England, Roscoe received an honorary M.A. degree from the University of Cambridge for his services to anthropological science, and lectured in the University on the anthropology of Africa. After a period of service as curate of Holy Trinity, he was presented by the University to the living of Ovington, which he held for the remainder of his life.

For eighteen years of his stay in Africa, Roscoe had been in close touch with Sir James Frazer. This association of field-worker and comparative anthropologist had proved little less fruitful on both sides than the similar association between Sir James and Baldwin Spencer in another field. In 1919 Roscoe was invited, through the efforts of Frazer, to undertake further work in East Africa as leader of the Mackie Ethnological Expedition under the ægis of a committee of the Royal Society. This was a one-man expedition, most of which was accomplished by bicycle. Roscoe visited a number of peoples on the Uganda-Congo border and on Mount Elgon, again keeping constantly in touch with Frazer by correspondence and report, as he maintained, to the great advantage of the work of the expedition. His results were embodied in three volumes, each with separate title, published in 1923, while a popular summary appeared as "The Soul of Central Africa". A general review of his life as missionary and anthropologist had already appeared in 1921 under the title "Twenty-five Years in East Africa". It is a book which by its restraint reveals the strength of his character.

WE regret to announce the following deaths:

Mr. Treacher Collins, formerly president of the Ophthalmological Society of the United Kingdom and of the International Congress of Ophthalmologists, known for his scientific investigations on the eye, on December 13, aged seventy years.

Prof. W. S. Thayer, emeritus professor of medicine in Johns Hopkins University, Baltimore, formerly president of the American Medical Association and president (in 1897 and 1913) of the International Medical Congress, known especially for his work on the pathology of the vascular system, on December 10, aged sixty-eight years.

News and Views

Warren Hastings and Science

MUCH has been written in the newspapers during the past week or so respecting the career of Warren Hastings in India, commemorative of the two-hundredth anniversary of his birth. Hastings was born on December 6, 1732, in Oxfordshire, and he died in 1818 at Daylesford, in Worcestershire. Little attention has been given, however, to Hastings' connexion with the world of science of his time. Six years after he had laid down office as Governor-General of India and had returned to England (1785), he was, on June 25, 1801, elected a fellow of the Royal Society. His certificate described him as a gentleman of great and extensive knowledge of various branches of science. He was living then in Berkeley Square, London. Among names appended in support were: James Rennell, Count Rumford, John Bruce, Caleb Whitefoord, and Mark Augustus Pictet. The first two were Copley medallists of the Society. Rumford's support of the ex-Governor-General of India is a particularly interesting feature of the candidature. In due course Warren Hastings attended and signed the charter book. It may be mentioned that in the last year of his administrative work in India, Hastings founded the Asiatic Society of Bengal, the first president of which was Sir William Jones. Though in itself nothing more than a coincidence, it is nevertheless of historic interest that the name of Capt. William Bligh, later (1805) Governor of New South Wales, who had accompanied Cook on his second voyage around the world, appears, along with Hastings, in the list of fellows elected into the Royal Society in 1801. His certificate was signed by Henry Cavendish and William Herschel, among others.

Centenary of Sir John Kirk

MONDAY next, December 19, marks the centenary of the birth of Sir John Kirk, naturalist, and exploring colleague of David Livingstone. Born at Barry, near Arbroath, Kirk was educated at the University of St. Andrews, graduating there in the medical faculty in 1854. He served on the civil medical staff during the Crimean War; afterwards, for six years as naturalist and second in command of Livingstone's exploring expedition in Africa. Entering the consular service, he became consul-general at Zanzibar (1873), and ultimately (1880), political agent. In the latter capacity his influence was of high importance in the administrative affairs of East Africa. Kirk accompanied the Sultan of Zanzibar on a visit to England in 1875, a treaty for the abolition of slavery in that potentate's dominions having been concluded. Sir David Prain has recorded that Kirk's memory is perpetuated in many ways: geographers allude to the Kirk Range, west of the Shire River; zoologists to Kirk's gazelle; and botanists to the genus *Kirkia*. Kirk was elected a fellow of the Royal Society in 1887, and the Royal Geographical Society awarded him its patron's medal in 1882. Kirk was created G.C.M.G. (1886) and K.C.B. (1890). He died on January 15, 1922.

The Dyestuffs (Import Regulations) Act

IN the House of Commons on December 8, an amendment for the omission of the Dyestuffs (Import Regulation) Act from the Expiring Laws (Continuance) Bill was defeated at the committee stage by 196 votes to 59. Replying for the Government during the debate, Dr. E. L. Burgin, Parliamentary Secretary to the Board of Trade, stated that the Government is still fully alive to the necessity of maintaining a flourishing dyestuffs industry in Great Britain, and referred to the definite cleavage of opinion between the users and makers of dyestuffs revealed in the third report of the Dyestuffs Industry Development Committee. This difference of opinion has been duly considered by the Government, and it is proposed to accept neither the majority nor the minority recommendations of the Report, but to extend the operation of the Act for a further year, during which period the Import Duties Advisory Committee will be asked to inquire into the whole circumstances of the dye industry and how the general interest may best be served. The whole matter will be referred to an impartial committee with all kinds of expert opinion available to it. When the Advisory Committee has reported it will then remain the duty of the Committee of Imperial Defence to intimate how the essential interests of national defence will be affected by any recommendations which may be made. The matter cannot be regarded as a purely industrial question. In the course of his speech, Dr. Burgin referred to the enormous advantage to Great Britain of the inclusion of the British dyestuffs industry within the international agreement between the German, French, Swiss and Italian makers. Careful inquiry has satisfied him, he said, that in regard to price the international agreement is not operating disadvantageously to Great Britain and the gold prices of the same colour do not vary to the disadvantage of the country.

Prevention of Distemper

THE inquiry into the causation and prevention of dog distemper started in 1922 has now been brought to a successful issue by the *Field* Distemper Council, Dr. P. P. Laidlaw and Mr. G. W. Dunkin, the Medical Research Council and the staff of the Wellcome Foundation at Beckenham. The disease has now been accurately defined and distinguished from other dog illnesses with which it used to be confused; it has been shown to be due to an ultramicroscopic virus and efficient methods of prevention have been worked out in the laboratory and confirmed in large-scale practical trials on packs of foxhounds and other dogs. Dogs are first given an injection of an emulsion of the organs of an animal which has died of acute distemper in which the virus has been killed with dilute formalin; in response, the animal develops a moderate degree of resistance which makes it possible, a fortnight later, to give it a dose of live virus which stimulates the animal to become definitely immune. The blood serum of such immune animals

can protect against the virus and is of use in treating cases of the disease and also in making a vaccinating mixture with live virus, which has the practical advantage of needing only one dose instead of two. These immunological reactions also make it possible to identify the disease with far greater certainty, and the new methods of prevention are available for ferrets, silver foxes, fitches, minks, etc., in which it has been found to occur.

Halley Stewart Laboratories of Physical Research

IT seems to be a remarkable coincidence that during the past century much of the research by the professors of physics in King's College, London, has been directly applicable to distant communication. Wheatstone appears to have been the pioneer and is known to all by his ingenuity and his discoveries which led to the invention of telegraphy. Maxwell, whose genius covered a wide range of study, is best known for work which is the theoretical basis of wireless transmission to-day. Richardson's work on the emission of electrons from hot bodies is applied in every wireless set. To-day, Appleton is in the forefront of the workers who are studying conditions in the upper atmosphere which control wireless transmission. But however comfortably his predecessors may have worked in the friendly atmosphere of the College, the conditions have so changed in the surroundings that Prof. Appleton finds himself obliged to work in a continuous electromagnetic storm—an atmosphere unsuitable to the character of the work in which he, his colleagues and his students are engaged. The work is already past the stage of a direct study of the conditions of wireless communication and has become of great importance in the study of the structure and nature of the upper atmosphere. By the refraction of wireless waves within the upper atmosphere, information is being obtained about the distribution of ionised regions. Thus hypotheses already applied in other branches of geophysical work come within the reach of direct experimental investigation.

THE problems which Prof. Appleton is attacking are of great complexity and it is clearly desirable not to add to the difficulty by working in a region so disturbed electrically as the Strand. Thus the generosity of the Halley Stewart Trust in providing new laboratories at Chesterford Gardens, Hampstead, is very opportune and is welcomed by the College and especially by the Physics Department. The work now in progress involves observations of a protracted nature—often over twenty-four hours—so that the convenience of a special laboratory with the director of research housed on the spot cannot be overestimated. The other branch of research to be undertaken in the building is concerned with the physical problems arising in the medical application of radium. This work is proceeding apace in London and one of its objects is to introduce scientific accuracy into the therapeutic use of radioactive substances. Already a number of students working under the direction of Dr. H. T. Flint are engaged in King's College and in Westminster Hospital Annexe on urgent problems in this branch of physics. The proximity of the new laboratories to Westminster Hospital Annexe will still further promote the close co-operation of the work in the two places.

Protein Swelling and Allied Phenomena

A CONFERENCE devoted to the subject of protein swelling, held under the auspices of the British Section of the International Society of Leather Trades Chemists, was held on December 1 at the Leathersellers' Hall, London, E.C.3. The introductory address was given by Prof. F. G. Donnan on the theory of membrane equilibria and the osmotic pressure of protein gels, in the course of which points connected with the Procter-Wilson theory of osmotic swelling were touched upon, and attention directed to the difficulty of applying this theory quantitatively to close-packed micellar systems such as hide. Mr G. S. Adair dealt with the osmotic pressure of the proteins, and described the assistance afforded by analysing such pressure into two partial pressures, one due to the protein ions and the other to the unequal distribution of ions. Dr. H. Phillips discussed the interaction of gelatin with acids and alkalis from the points of view of the electronic theory of valency and Bjerrum's *Zwitterion* constitution of amino acids. Mr. F. C. Thompson explained the two types of salt effect on the swelling of gelatin, one, an osmotic repressive effect on acid or alkali swollen gelatin, and the other a lyotrope effect on neutral non-ionised gelatin. Dr. R. H. Marriott, in his paper on swelling in alkaline solutions, put forward his views on the mechanism of the fixation of calcium by collagen, and the influence of the chemical constitution of keratin on its resistance to osmotic swelling.

THE more practical aspects of swelling and its bearing on leather manufacture were summarised by Dr. C. H. Spiers, who considers that plumping of hides is associated with a twisting and folding of the polypeptide chains in the crystallites of the fibrils. Dr. Dorothy Jordan Lloyd put forward explanations for the observed reductions in swelling power of proteins with increasing compactness of molecular organisation. The structure of wool keratin and its relation to swelling phenomena, was the subject of Dr. J. B. Speakman's paper, while the last paper was given by Mr. W. R. Atkin, on swelling in weak acids, in which it was pointed out that a careful consideration of Kuhn's work shows that the maximum swelling of gelatin in weak acid is at an external equilibrium of pH 2·4 in agreement with the earlier work of Procter.

Cinematograph Films of Cyclic Phenomena

MESSRS. DANCE-KAUFMANN, 18 Upper Stanhope Street, Liverpool, have produced some useful technical films which aim at the representation, by means of moving pictures, of phenomena which are cyclic, or may be considered so, for the purposes of exhibition. The operation of a diagram for the composition of rotating vectors; the summation of three alternating fields displaced in space and time;

or the action of the Oldham coupling are among the many subjects which are illustrated by the films. The diagrams appear as black lines on a lighted field, the dimensions of which are about 2 ft. by 1 ft. 6 in., with the 16 mm. film, and with a 50 watt projector; the visibility is sufficiently good with a shaded screen to provide for a class of thirty or forty students, and for a larger number in a darkened room. The fact that the films are in the form of endless bands and may be repeated indefinitely, and that the film may be arrested at any point for the purpose of measurement or explanation, should render them valuable for instruction in junior and for demonstration in senior classes. The range of films in the firm's catalogue is extensive and representative, including most branches of physics and engineering, and the presentment of the subjects is well considered. The cost of the films and projector is moderate and orders are accepted for special films to suit the requirements of individual lecturers. 35 mm., 16 mm. and 9·5 mm. films are available at the same price.

Gyroscopic Tops

AT the Friday evening discourse on December 9 at the Royal Institution, Prof. J. G. Gray discussed gyroscopic tops and combinations. After showing some preliminary experiments to illustrate the fundamental properties of the gyroscope, Prof. Gray proceeded to describe methods and technique he has devised for the production of self-erecting gyroscopes. Gyroscopes fitted axially with special point and ball pegs, mounted on cup supports, were shown to be self-erecting, the stability being the result of the special construction of the gyroscopes and their accessories. In some of the tops exhibited, devices called erectors are mounted on the casings of the gyroscopes; rotation of these erectors endows the tops with stability or instability according to the direction of rotation of the erectors. Generally speaking, an erector consists of a normally horizontal plate on which rest spherical masses, or to which masses are pivoted, the construction being such that when the top is vertical the masses, as a consequence of the rotation of the plate, dispose themselves symmetrically with respect to the axis of the top; but when the top is inclined to the vertical, and the plate to the horizontal, the masses move about relatively to the plate in such manner that, providing the plate is rotating in the direction of spin of the gyroscope, the top experiences an erecting couple, and thus becomes endowed with a sense of the vertical. Gyroscopic tops were shown which are self-erecting as a result of the special construction of the pegs on which their casings revolve. Further tops exhibited are rendered stable, or unstable, at will by rotation of the cups on which the pegs are supported. Members of this latter family of tops were caused to erect themselves from initial positions in which their axes of spin were horizontal to those in which their axes were vertical, and then to return to positions in which their axes were horizontal.

Development of the Electrical Industry

IN the third of the series of lectures on industrial affairs at the Imperial College of Science, Mr. Maurice Solomon discussed certain aspects of the electrical industry. He emphasised that further development of the industry would involve a more widespread use of electrical appliances in the household. Such appliances must be properly standardised so as to be readily interchangeable. Moreover, there must be standardisation of quality, for it is of the utmost importance that the user shall acquire and retain confidence in the safety and smooth working of electrical apparatus. As an indication of the extent to which electricity may be applied in the modern household, Mr. Solomon said that in his own house there are some twenty-eight different types of electrical appliance in use. The electrical industry is still young and there is no lack of appreciation of the importance of research in its future development.

Organisation and Co-operation in Industry

MR. SOLOMON then discussed the general proposition that the organisation of an industry into large firms or groups of firms is advantageous to that industry and to the general community. In Great Britain we have looked askance at the cartel as tending to the raising of prices and the stultification of progress through the elimination of competition. Actually, the cartel does not eliminate competition but merely reduces it to a reasonable level, and there is now a growing appreciation of the evils of unrestricted competition. In any event, competition is by no means the only incentive to progress: markets may be extended by fostering a wider public demand as well as by capturing the existing trade of competitors. Moreover, criticism by the public is an ever present incentive to progress, even in the case of a monopoly. On the other hand, the small concern which puts on the market a standard article at cut prices is taking advantage of the results of research which it could never have carried out for itself, and is thus shirking responsibility for the progress of the industry and for service to the community. A large firm or group of firms by efficient organisation can maintain a large output of products of a high and standard quality under conditions which enable those engaged in the industry to earn a reasonable living; and by control of production and prices, can minimise the evils arising from alternations of slump and boom. The co-operative research which an association of firms can undertake affords the key to future progress not only in the industry immediately concerned but also in cognate industries.

Television in the United States

IN the *Journal of the Television Society* for September, there is an interesting paper by Mr. A. Dinsdale on "Television in America To-day". He points out that those concerned with television development are either research workers or companies interested in existing equipment. For the last two years, the Bell Telephone Laboratories have been experimenting with a two-way television

system over telephone lines between two buildings in New York which are two miles apart. Even when perfected, it is not certain whether there would be a commercial demand by the public for a costly facility which would enable them to see the person telephoning. At the General Electric Company's laboratories at Schenectady, experiments are being made on the transmission of television signals along a light beam instead of by wire or radio. Nothing very novel has recently been published in connexion with cathode ray television. The National Broadcasting Company is building a new television studio on the eighty-fifth floor of the Empire State Building at a height of 1,000 feet above the street. The short-wave transmitting aerial is on the top of the airship mooring mast and is 1,250 feet above the street. The received images will be six inches square and will be seen directly on the end of a cathode ray tube. Transmissions will be made from the Empire State studio on wave-lengths of 5–7·5 metres.

Supply Undertakings and the Grid

IN an article in the *Times Trade and Engineering Supplement* for November 19, Mr. Charles D. Taite, of the Lancashire Electric Power Company, discusses the grid from the point of view of the supply undertakings affected by it. We are glad to learn that the supply undertakings, several of which strongly opposed the Act of 1926, are now willing to co-operate with the Central Electricity Board in making the schemes which have been carried out under the provisions of the Act a success. This is wise, seeing that they pay the whole of the charges in connexion with the grid and are therefore vitally interested in its success. Since the Act came into operation, a wave of industrial depression has swept over the world and although the use of electricity in Great Britain has continued to expand, the growth is less than it would have been under normal conditions. In some areas, factories have closed down. In textile areas, many mills have gone permanently out of commission. On the Clyde and the Tyne, shipbuilding has fallen on evil days. On the other hand, new openings have been found for electrical development; rural electrification has commenced and electricity is being more widely used by the householder. But beneficial as these developments are, their effect is comparatively insignificant compared with the enormous growth which would take place with a return to good trading conditions. Some indication of what might be expected was experienced in the textile areas of Lancashire last autumn, following the revival which took place in the demand for textile goods. The load on many undertakings expanded by 15 per cent, and had the revival been maintained throughout the year, another 15 per cent improvement would have been reached. The heavier the load the less will the supply companies' fixed charges per unit to the Central Electricity Board be and the cost of electricity would be cheaper. In Mr. Taite's opinion, there is still an almost unlimited field for electrical enterprise.

Outdoor Museums in the United States

PUBLIC museums in the United States of America have been increasing in numbers in recent years at the rate of one every fortnight, and their standard of efficiency as educational agencies has been rising. The American Association of Museums has been taking stock of the museum resources of the country, and has made available a considerable mass of new statistical information on which the Association's director, L. V. Coleman, has based an interesting report on "Recent Progress and Condition of Museums". This has been published by the United States Office of Education as Bulletin No. 30, 1931. Among recent developments is the appearance of museums of science in national parks. The underlying idea of these is that museums attempt, too often without success, to tell indoors, with the aid of objects that are fragments or imitations, stories that should be told where Nature has provided genuine illustrative exhibits. 'Trailside' museums, each given over to a restricted subject, are found to be more useful for some kinds of instruction than cases in a museum building. The first demonstration was made a few years ago in the Yosemite, and the most recent is an extensive series of 'trailsides' in the Yellowstone National Park. Simultaneously with this exploitation of the resources of the national parks, museums in cities have been moved to search local parks for natural features that can be explained on the spot. The influence of the movement has spread into the field of history also, as in the George Washington birthplace national monument, and a newly appointed park historian is developing history education, just as the park naturalist has developed natural history education. The number of museums doing good educational work a decade ago was not more than a dozen; now it is in the hundreds.

The Auckland Museum and Institute, New Zealand

THE Auckland Institute and Museum, now in its second year of occupation of the fine Memorial Building, has of necessity been undergoing a revision of its extensive collections. But in addition it has been able to carry out a very successful expedition for the investigation of the natural history and ethnology of the northernmost portion of the North Auckland peninsula (Annual Report for 1931–32). Another notable activity of the staff is the furthering of the educational side of the Museum by lectures within the building and in the district, the Sunday afternoon public lectures having proved specially attractive; as well as by the formation of clubs for boys and girls, the preparation of exhibits for schools, and the arrangement of special exhibitions. An exhibition of antique plate, chiefly of the seventeenth and eighteenth centuries, increased the attendance by a thousand a week during its course; the weekly average number of visitors throughout the year was 2,856. The membership, like that of most similar bodies, shows a slight falling off in numbers, but the present roll still includes 588 names, 157 representing life members with a capital subscription fund exceeding £2,000.

The Problem of Wilkes Land

IN the United States Exploring Expedition of 1838 Charles Wilkes reported various landfalls near the antarctic circle south of the Indian Ocean. A number of soundings also showed a continental shelf. On this evidence, Wilkes suggested the existence of an antarctic continent and the lands were long referred to collectively as Wilkes Land. D'Urville at the same time found Adélie Land, which appeared to be part of the same coast-line. Subsequent explorations in these waters, principally by Capt. R. F. Scott and Sir Douglas Mawson, failed to establish all Wilkes's landfalls in the position originally assigned. This had led to the suggestion that he was mistaken and the tendency is to restrict the use of the name, Wilkes Land. Prof. W. H. Hobbs in an article in the *Geographical Review* for October 1932 discusses this problem and publishes a map on which subsequent discoveries have been printed over those of Wilkes. If Wilkes's latitudes were wrong in many cases, his longitudes show considerable correspondence to actual land. Pack-ice prevented his close approach and the distance of his 'lands' had to be estimated. Allowing for the liability to underestimate distances in the remarkably good visibility, and the lack of cross-bearings to fix position, Prof. Hobbs argues that recent work has re-established Wilkes Land in the wider sense and exonerated Wilkes from the charges that have been brought against him. The name is a useful one to embrace many small lands and might well be retained.

Radium from Canadian Pitchblende

THE Industrial Information Bureau of Canada announces that a new commercial process of radium extraction has been successfully accomplished by R. J. Traill and W. R. McClelland of the Department of Mines at Ottawa. On account of the high-grade character of the pitchblende ores from the Great Bear Lake area, and partly because of the simplified technique that has been developed, it is believed that the costs of radium production will be considerably less than has hitherto been practicable. Instead of some forty operations involved in the Belgian method, radium salts can now be produced in the Government Laboratory with less than half that number of steps and in six weeks instead of three months. The chief cost in radium separation arises from the necessity of using about three tons of chemicals for the treatment of every ton of ore. The new process has been adapted to treat with almost equal success both siliceous ore and the silver carbonate ore with which pitchblende is found associated in the Great Bear Lake field. Ten tons of ore are estimated to produce about 1 gm. of radium. Already some 4,000 gm. of radium concentrates have been extracted in the preliminary experimental work. Canada's first radium refinery is now being established at Port Hope, Ontario, to which point the ore will be brought for the extraction of radium and various by-products such as uranium, lead and silver.

The Personality of Britain

THE valuable synthetic study of prehistoric Britain as an environment of man which Dr. Cyril Fox delivered as a lecture to the First International Congress of Prehistoric and Protohistoric Sciences (see NATURE, Aug 13, p. 247), has now been published by the National Museum of Wales under the title "The Personality of Britain: its influence on Inhabitant and Invader in Prehistoric and early Historic Times" (Cardiff: National Museum and Press Board of the University of Wales, pp. 84, price 2*s*. 6*d*.) In a preface, Dr. Fox points out that publication has been undertaken appropriately by the National Museum since not only does Wales form an integral and important part of the highland zone which he differentiates in the course of his argument, but also characteristic examples of the objects of material culture with which he deals may be seen in the galleries of the Museum. The value of the text as published is much enhanced by a full series of distribution maps, most of them based on material which Dr. Fox himself has collected in the course of the past five years and in the preparation of which he has had the assistance of Miss L. F. Chitty. Archæologists will be grateful to the National Museum of Wales for having so speedily made accessible this valuable and comprehensive study of the influences of geographical environment in Great Britain between *circa* 2500 B.C. and A.D. 1000.

Tea Cultivation

TEA is an unusual crop from the point of view of the cultivator because it is necessary to keep the bush in vigorous vegetative growth and at the same time continue to remove the young vegetative shoots, which are plucked by breaking them off with the thumb and forefinger, the bud and the next two open leaves being thus removed. Naturally, therefore, pruning methods, manurial treatments, etc., will be controlled by different considerations than where an orchard tree is cultivated for its flower and fruit production. Interest is now being taken in the cultivation of tea in Malaya, where the central highland regions are being opened up. Mr. E. A. Curtler was therefore sent on tour to Ceylon and India to obtain the most recent information on methods of tea cultivation and manufacture, and his impressions and experiences are embodied in an interesting publication of the Department of Agriculture of the Federated Malay States (General Series No. 9, 1932).

The Psychology of the Family

DR. PRYNS HOPKINS, in the *Sociological Review*, vol. 24, No. 2, considers the psychology of the family. He reviews the nature of the chief instincts concerned and he stresses their liability to fixation at, or regression to, any of the numerous stages in their development. Consequently, he suggests that in the pre-marital state, moderate promiscuity should be sanctioned as most likely to promote healthy and complete development, and wise choice of the permanent partner. In the

marital state, he insists that the sole bond must be that deep affection which may be a concomitant of desire, and is the cause and justification of monogamy. Finally, he pleads for frankness towards children in matters of sex, and asserts that those who do receive this from parents obviously fond of them, and not strained in their personal relationship, are most likely to grow up healthily and happily. The greater freedom for experiment which he demands that society introduce into the convention of the family is well supported by his argument. The paper is naturally controversial, but it would benefit by the suppression of the sentimental note which is occasionally apparent.

King's College (London) Engineering Society

THE "King's Engineer", the annual of the Engineering Society and the Engineering Branch of the Old Students' Association of King's College, London, which has recently been published, is one of the most interesting publications of its kind and affords evidence of the engineering activity of the College. Fourteen papers were read by the members of the Engineering Society during the year, and four of these are reprinted in the annual. The paper on the "Development of High-Speed Compression Ignition Engines", by V. H. F. Hopkins, was the prize essay. Another paper of considerable interest is that by A. H. Jenkins on "China-Clay and China-Clay Mining in the West of England". The number is issued as a memorial volume to Prof. Ernest Wilson, who for more than thirty years was professor of electrical engineering, and who endeared himself to all King's College students. Prof. G. Cook gives an appreciation of Prof. Wilson's work, and a list of his papers.

Survey of India

THE Survey of India has published its report on map publication and office work for the year ending March 31, 1931 (Calcutta, 1932. 1 rupee). The most important part of the publication is the series of index maps of all the maps of India, including the 'Million Map' sheets. Practically the whole of India, but not Burma, and also Afghanistan, Baluchistan and Persia now appear on the useful southern Asia series of one in two million, while the greater part of India is also published on the one to a million scale of the Carte Internationale du Monde. The larger scale maps make good progress and some two hundred new sheets on different scales have been published during the year.

Electric Supra-Conduction in Metals

PROF. J. C. MCLENNAN writes as follows: "It is regrettable that in my article on 'Supra-Conduction in Metals' published as a supplement to NATURE of December 10, there were two undetected typist's errors that should have been corrected. In the third section of the article the words 'copper sulphate' should read 'copper sulphide' and in the last section the words 'wire lattice' should read 'ionic lattice'. It may be of interest to state here, too, that Prof. R. de L. Kronig's paper on the electron lattice theory of supra-conduction in metals appeared in the *Zeitschrift für Physik*, Bd. 78, Heft. 11 and 12."

Announcements

THE annual meeting of the British Association will be held next year in Leicester on September 6–13 under the presidency of Sir F. Gowland Hopkins, president of the Royal Society. The following sectional presidents have been appointed: Section A (Mathematical and Physical Sciences), Sir Gilbert Walker; B (Chemistry), Prof. R. Robinson; C (Geology), Prof. W. G. Fearnsides; D (Zoology), Dr. J. Gray; E (Geography), the Right Hon. Lord Meston; F (Economic Science and Statistics), Prof. J. H. Jones; G (Engineering), Mr. R. W. Allen; H (Anthropology), the Right Hon. Lord Raglan; I (Physiology), Prof. E. D. Adrian; J (Psychology), Prof. F. Aveling; K (Botany), Prof. F. E. Lloyd; L (Educational Science), Mr. J. L. Holland; M (Agriculture), Dr. A Lauder.

MR. J. BERNARD CALKIN, Wychwood School, Bournemouth, states that in his letter entitled "Implements from the Raised Beach at Slindon Park, Sussex" (NATURE, Nov. 26, p. 813) the reference "to the Cannon shot gravels as being of interglacial age was an oversight. As they are actually a glacial deposit, I conclude that most of the Slindon beach belongs to the preceding interglacial period."

IN commemoration of the seventieth birthday of Sir P. C. Rây, founder, foundation-president and patron of the Indian Chemical Society, a jubilee volume, of some 350 pages, is being published by the Society, containing contributions from many eminent chemists in India and abroad. Orders for the volume should be sent to the Honorary Secretary, Indian Chemical Society, P.O. Box 10857, Calcutta.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A head of the Chemistry Department of the Municipal Technical College of Kingston-upon-Hull—The Director of Education, Education Offices, Guildhall, Hull (Dec. 31). A librarian and keeper of records in the Department of Antiquities, Palestine—The Director of Recruitment (Colonial Service), 2, Richmond Terrace, Whitehall, London, S.W.1 (Dec. 31). An examiner in domestic science and assistant examiners in mathematics, chemistry and other subjects for the School Certificate Examination for 1933 of the Central Welsh Board—The Clerk to the Central Welsh Board, Cardiff (Jan. 14). A head of the Civil and Mechanical Engineering Department at the Northampton Polytechnic Institute, St. John Street, London, E.C.1—The Principal (Jan. 20). A professor of experimental physics at the Queen's University of Belfast—The Secretary (March 18). A professor of zoology at the University of Leeds—The Registrar. A secretary to the Society for Cultural Relations between Great Britain and the U.S.S.R.—The Chairman, S.C.R., 1, Montague Street, London, W.C.1.

Letters to the Editor

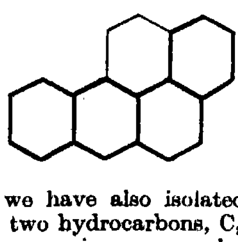
[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Coal Tar Constituents and Cancer

THE nature of the cancer-producing constituent (or constituents) of coal tar has been under investigation in this and other laboratories for some years past, but hitherto no known constituent of tar has been found to have definite cancer-producing properties, and no new carcinogenic constituent has been isolated. The isolation has now been accomplished by concentrating active fractions of coal-tar pitch, making use of the method of fluorescence spectroscopy introduced here by W. V. Mayneord. This brought to light a spectrum which was found to be common to many carcinogenic mixtures.[1] The methods adopted have included fractional distillation, solvent extraction, and crystallisation of picrates and of the products of their decomposition with alkali.

In this way a very active carcinogenic hydrocarbon has been obtained, which in the pure state has the typical fluorescence spectrum to which reference has been made above. For reasons which cannot be detailed here, we formed the opinion that this hydrocarbon was possibly 1 : 2-benzpyrene. This compound was unknown, but has now been synthesised here from pyrene by way of β-1-pyrenoylpropionic acid, γ-1-pyrenylbutyric acid, and 4′-keto-1′: 2′: 3′: 4′-tetrahydro-1 : 2-benzpyrene. The synthetic sample of 1 : 2-benzpyrene produced cancers of the skin in mice just as rapidly as the material isolated from pitch.

The tumours appeared, so far as can be judged from the limited number of experiments on mice yet carried out, in approximately half the time required for tumour production by 1 : 2 : 5 : 6-dibenzanthracene, so that 1 : 2-benzpyrene is much the most active carcinogenic hydrocarbon yet known. We do not claim that this is the only carcinogenic compound present in coal tar. The relationship of this new hydrocarbon to 1 : 2-benzanthracene, the parent substance of the group of cancer-producing hydrocarbons already described,[2] is shown by its structural formula, the benzanthracene ring-system being indicated by heavy lines:



In addition, we have also isolated from coal-tar pitch the other two hydrocarbons, $C_{20}H_{12}$, composed entirely of benzene rings; namely, perylene and 4 : 5-benzpyrene. The identification of the latter hydrocarbon was effected by synthesis. Moreover, we have isolated 1 : 2-benzanthracene from the chrysene fraction of coal-tar. None of these four hydrocarbons had previously been recognised as a coal-tar constituent. A more complete account of these experiments is being prepared for publication.

We gratefully acknowledge our indebtedness to Prof. E. L. Kennaway for his helpful encouragement during a somewhat long and arduous task.

Tribulosis and Methæmoglobinæmia in South African Sheep

IN the investigation of the disease 'tribulosis' or 'geeldikkop' (literally, 'yellow-thick-head'), which causes heavy mortality among sheep in the Karroo area of South Africa, it was observed by one of us[1] that death from methæmoglobinæmia followed administration of the press juice of the plants held responsible for the causation of the disease. Animals grazing upon different *Tribulus* species (Zygophyllaceæ) at certain periods of the year (summer months) evince a marked photosensitivity accompanied by more or less intense icterus. The swellings of the lips, ears and head, those parts least protected from the sun's rays, are followed by necrosis and mummification of these parts, which may be so intense that the animal is quite unable to eat or drink. Death follows from inanition, toxæmia and jaundice.

Methæmoglobinæmia has never been recorded as a clinical symptom. With the exception of the jaundice, the clinical picture very closely simulates that produced by experimental *Hypericum* or hæmatoporphyrin sensitisation.[2]

The rôle of the plants mentioned in causing the disease has been established by feeding tests carried out at the scene of an outbreak, but so far no clue as to the nature of the toxic substance responsible has been obtained, neither has the disease been produced experimentally outside the areas in which it normally occurs. Outbreaks are very spasmodic, even capricious, in appearance. It is felt by us that a certain set of physiological conditions is necessary, both of the plant and of the animal, for the characteristic syndrome to develop.

In testing the toxicity of *Tribulus* plants at Onderstepoort, death invariably resulted from methæmoglobinæmia within 3–4 hours of dosing (by stomach tube) with the freshly expressed juice of the green plant, or water extracts of the dried, powdered material. Although the symptoms of such poisoning differed markedly from those of the disease as it is seen in the field, it was decided to attempt the isolation of the responsible substance.

We have succeeded in proving that the formation of methæmoglobinæmia is due to nitrite, not present as such in the plant, but formed from nitrate by an extremely active reducing system.

Determinations of nitrate content by the method of Strowd[3] (except that extracts were made with boiling water), showed that our dried, powdered samples of *Tribulus* plants from various localities contained between 3·2 and 2·2 per cent, reckoned as KNO_3, on the dry weight basis. Since conversion of nitrate to nitrite and reaction of this with amino bodies, etc., takes place during the drying process, the actual amount of nitrate in the fresh plant is

probably considerably greater even than these figures indicate.

Crystalline potassium nitrate was isolated from the material in fair yield. The enzyme system appears to be insoluble or bound to the denatured proteins and it was found possible to wash the plant powder free from nitrate and then to effect enzymic reduction of added nitrates. Reduction may proceed slowly, beyond the nitrite stage, and the various intermediates, such as hydroxylamine, have been under consideration as possible toxic factors.

By analogy with the work of Warburg and Negelein[4] upon the alga *Chlorella pyrenoidea*, it may be assumed that reductive processes are so controlled in the living tissues of the higher plant that nitrites are not produced in any appreciable concentration from the reduction of nitrates. Nitrite may be looked upon as a product of a deranged metabolic activity. This explains why methæmoglobinæmia is not observed clinically in sheep grazing upon living *Tribulus* plants.

Incidentally, we have also demonstrated that if fairly large doses of nitrates are given by stomach tube to normal sheep, the reducing activities of the bacteria, yeasts, etc., in the rumen may be great enough to produce sufficient quantities of nitrite to cause death from typical methæmoglobinæmia: for example, with daily doses of 10–20 gm. in two to three days.

What relation, if any, this toxic factor present in *Tribulus* plants bears to the causation of the disease 'tribulosis' we are not at present prepared to say. The fact that, in both, pronounced hæmoglobin changes, in one case leading to methæmoglobin formation, in the other to excessive bile pigments, are the predominant pathological findings, may be of some significance. On the other hand, we have failed to reproduce either the photosensitivity or the icterus of 'tribulosis' by prolonged administration of dried *Tribulus* plants, potassium nitrate, potassium nitrite, hydroxylamine hydrochloride, hydrazine sulphate and ammonium carbonate either alone or in combination.

'Geeldikkop' is apparently not caused only by species of the genus *Tribulus*, since an identical condition, usually of less severity, has been observed in areas where no *Tribulus* grows, and in these cases, lucerne, *Panicum* spp, *Setaria* spp. and possibly other widely differing plants have been incriminated.

For these reasons we believe that the true causative factor of 'tribulosis' is not a specific substance, peculiar to the genus *Tribulus*, but, as stated, we are inclined rather to the view that some simple substance arising either in the animal or the plant as a result of disordered metabolism, possibly through wilting, and acting in conjunction with a peculiar set of conditions, are to be held responsible for the disease.

Normally the plant is an excellent fodder plant. We would welcome any suggestions or comments that would help to throw light upon this obscure and involved problem.

Photochemical Reaction of Hydrogen and Chlorine

THE recent appearance of a note by W. H. Rodebush and W. C. Klingelhofer[1], in the course of which they mention that they find water vapour to have no effect on the length of the chain reaction induced in a mixture of hydrogen and chlorine by chlorine atoms, suggests to us that a mention of experiments of our own of a similar nature would be of interest to others. Like the above authors, we were aware of the results of Prof. Bodenstein, who courteously informed us last May that, in the course of comprehensive experiments, he had been unable to inhibit the photochemical reaction of hydrogen and chlorine by intensive drying.

The first indications of this sort in our case were noticed in the summer of 1930,[2] when the reaction in question was found to proceed without hitch at chlorine pressures so low as 0·012 mm., a figure controlled by immersing a side tube of the apparatus, containing solid chlorine, in a bath of melting allyl chloride (136·6° K.). The vapour pressure of ice at this temperature is of the order of 10^{-8} mm., apart from the possible formation of chlorine hydrate. The soda-glass apparatus was well evacuated and baked out before use. Subsequent work during the last two years under similar, though modified, conditions has always given the same type of result. As, however, there was the possibility of slow distillation of water vapour through the reaction zone from some part of the apparatus which had been insufficiently baked out, and, in particular, as in many of our recent experiments we had employed taps lubricated with phosphoric acid (private communication from Mr. D. L. Chapman) it was decided to submit the point to a more rigorous test.

The soda-glass apparatus was provided with a sealed-in palladium tube at the end remote from the pumps, and the whole, including the Pirani gauge (Rollefson's pattern) was thoroughly baked out in a rapid stream of hydrogen admitted through the palladium. The prevailing pressure of this gas during the process was of the order of 1 mm. After cooling in the gas stream and evacuating, chlorine was distilled into a side tube immersed in liquid air, the greater part of it distilled out again, and liquid air replaced on the side limb. The baking out in the hydrogen stream of the whole apparatus, with the exception of the chlorine supply tube, was repeated for eight hours at a temperature of 200° C., and the apparatus was sealed off from the pump whilst the hydrogen stream was still running. After cooling, the liquid air on the chlorine supply was replaced by a bath of melting methyl-cyclohexane (p_{Cl}, 0·11 mm.), and the apparatus, which contained about 0·5 mm. of hydrogen, insolated by light from a metal filament lamp filtered through a 5 mm. glass plate. Several successive runs gave perfectly normal reaction rates. Blank experiments showed that any formation of hydrogen chloride at the palladium tube surface was negligible.

Dependence of Electrical Conductance and Dielectric Constant upon Frequency in Mixtures of Strong Electrolytes

THE properties of the ionic atmosphere in the new electrostatic theory of strong electrolytes are very important in regard to reversible thermodynamic and irreversible processes.[1] They enable us, for example, to develop a theory of the irreversible conductivity processes and of the irreversible mechanism that is involved in the viscosity phenomena in the case of a simple electrolyte. We have recently been able to find the general relation between frequency and electrical conductance and dielectric constant in mixtures.[2] From our general equation of the force of relaxation one can now derive a detailed discussion of the quantitative limiting laws of the conductivity and the dielectric constant in mixtures of strong electrolytes. The special discussion—for example, of the problem of 3-ions and 4-ions and so on—is very complicated and will occupy some time.[3]

We thought it desirable, however, to give at once a theoretical explanation of the new experimental work done by Spaght.[4] Spaght has inquired into the dispersion of the conductance of two mixtures of strong electrolytes. His results can be explained theoretically—in a qualitative manner at least—by a further generalisation of the calculations made by Bennewitz and Wagner-Küchler, who have worked out only the stationary case, where a relatively small quantity of ions of sort (3) are mixed with an electrolyte consisting of ions of sorts (1) and (2). Our calculations deal with the non-stationary case and give the expression for the mobilities and the dielectric constant of an electric field alternating with high frequency. Even in this simple case, the expressions for the electrical conductance and the dielectric constant are relatively complicated. We will not give this expression now, as it will be published shortly.[5]

It would be very interesting to compare the theoretical results with further systematic experimental studies which will have to be carried out in the future. In the case of a simple electrolyte, this has been done successfully by many workers who obtain quantitative agreement with the theory of Debye-Falkenhagen. (See the monograph by Falkenhagen, loc. cit.) It should be possible to investigate not only the dependence on frequency of the electrical conductivity but also that of the dielectric constant effect by means of the method worked out by M. Wien.[6] The latter effect is based on the fact that we have a phase difference between the field strength and the ionic velocity produced. That means an electric field produces two components of the electrical current; one of them has the same phase as the field strength and the other one is in phase with the differential quotient of the field with respect to the time or the Maxwell displacement current. The quantity of the displacement current is proportional to the dielectric constant. Hence we get an alteration of the dielectric constant (relatively to the dielectric constant of the pure solvent) which is dependent on the frequency of the field.

It is easy to see that we have to deal with an increase of the dielectric constant. Consider a quick displacement of a central ion; the consequence of the finite time of relaxation of the ionic atmosphere is that a quasi-elastic force will arise which will repel this central ion to its original position. This quasi-elastic binding between the ions means an increase of the dielectric constant. In the case of more concentrated solutions and relatively very high frequencies, there will be, of course, other interesting effects on the conductance and the dielectric constant, for example, the quantum mechanical forces, dipole effect, effect of solvation and so on.

One important point of view in the development of the theory of electrolytic solutions has yet to be considered. The Debye theory is applicable only in the case of sufficiently dilute solutions and gives the quantitative limiting laws. The electrostatic theory makes use only of the Coulomb forces between the ions. Not only are the electrostatic forces, which means the Coulomb forces and the forces of polarisation, significant, but also the quantum mechanical forces and the interionic dispersion forces are of great importance. The latter correspond to the van der Waals' forces in the case of gases and are not only of electrostatic nature but also of quantum mechanical nature in the sense of London, Eisenschitz and Margenau.

Taking into account these ideas one has to replace the interionic forces *in vacuo* by the corresponding forces in a solvent; that means that in the first approximation one has to substitute e^2/Dr for e^2/r in the formulæ developed by the quantum mechanics, where D is the dielectric constant and e the electric charge.

It would be very interesting to extend the theory in this direction. We believe that it would be possible to develop a statistical treatment of more concentrated solutions in the sense mentioned above. This is one of the most interesting problems in the field of electrolytic solutions.

Infra-Red Absorption of Quartz

IN 1895 Merritt,[1] observing the infra-red absorption in the $2 \cdot 9\,\mu$ region of a beam passing at right angles to the axis in crystalline quartz, found a definite difference when the radiation was polarised in planes at right angles and parallel to the axis. That is, the ordinary and extraordinary rays respectively were differently absorbed. The absorption of a beam parallel to the axis was, as was to be expected, similar to that of the ordinary ray in the first case. Koenigsberger[2] in 1897 made like observations.

I am unaware of any subsequent investigation of this effect in this region and wish to direct attention to its importance, especially as the absorption bands for radiation passing parallel to the axis may be required to serve as standards of wave-length in the infra-red. Dreisch[3] has published a curve showing four bands in this region though he only states the wave-lengths of three of them.

I have recently examined specimens of quartz with

unpolarised radiation passing parallel and at right angles to the axis and have been fortunate in having available, by the courtesy of Messrs. A. Hilger Ltd., unusually large thicknesses of the material. The differences in both intensity and structure of the bands for the two directions are striking as may be seen from Fig. 1. The figure also shows the curve of galvanometer deflections (III) using a small 'hohlraum' as source. The bands recorded by Dreisch for crystalline quartz parallel to the axis appear in this curve and are due to the prism, which was of quartz. There is an apparent wave-length discrepancy between curves I and III, because I is referred to a horizontal datum and III to an energy curve falling fairly steeply to the right. This causes an apparent displacement of the bands in III to the right.

It appears, from curve I, that the ordinary ray is completely absorbed between $2 \cdot 83\,\mu$ and $3 \cdot 02\,\mu$ in 63 mm. of quartz. In the 83 mm. used for curve II there is nevertheless a measurable fraction of radiation transmitted, which must be ascribed to the extraordinary ray. Allowing for a 50 per cent initial loss from the beam by absorption of the ordinary ray, it follows that the general intensity of absorption of the extraordinary ray must be considerably less than that of the ordinary ray in this region. Further, a comparison of curves II and III suggests that the band structures will prove different. The wave-length of maximum absorption of a band will therefore vary with the direction and state of polarisation of the beam in the quartz. The differences extend some distance on each side of the region mentioned, although here they are not so directly interpreted, and it is interesting to note that Barnes[4] has recently obtained indications of similar dichroism in the band at $38\,\mu$ in the far infra-red.

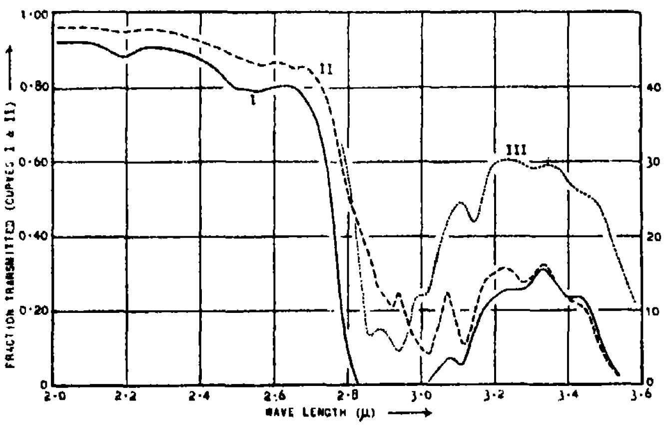

FIG. 1.—Infra-red absorption of quartz. I. Path 63 mm. parallel to axis. II. Path 83 mm. perpendicular to plane of optic and electric axes. III. Galvanometer deflections without specimen.

In curve I the band at $3 \cdot 11\,\mu$ is, I think, to be identified with Dreisch's fourth band, the wave-length of which he does not state. The bands at $2 \cdot 19$, $3 \cdot 27$, and $3 \cdot 41\,\mu$ as well as some structure between $2 \cdot 5$ and $2 \cdot 7\,\mu$ have not, so far as I know, been recorded before. I have also found a band in fused silica at $2 \cdot 23\,\mu$ which is of a similar order of intensity to that at $2 \cdot 19\,\mu$ above. This is interesting in view of Barnes's results (loc. cit.) indicating bands in fused silica in the far infra-red which, it is suggested, are in some way related to bands occurring in crystalline quartz at rather shorter wave-lengths.

Further work on this subject has been unavoidably held up for some months but I hope shortly to carry out a more extensive investigation of the effects using polarised radiation.

Electrical Ignition of Explosive Gaseous Mixtures

PROF. TAYLOR-JONES, in discussing the thermal theory of the electrical ignition of explosive gaseous mixtures, states that "There is nothing in the thermal theory . . . to suggest that the energy of the translational motion of the molecules, or that of their rotational or vibratory motion plays a preponderating part in the process of ignition" ("Induction Coil Theory and Applications", Pitman, London, 1932). Whilst in complete accord with the first part (up to and including "theory") I cannot agree with this statement as a whole, for the following reasons:

The thermal theory of electrical ignition has been put forward by Taylor-Jones, Morgan and Wheeler[1] in terms stating that "the ignition of a gaseous mixture depends primarily . . . on the heating of a sufficient volume to a sufficient temperature". But this view must involve the supposition that internal molecular energy plays no rôle in ignition, because it is well known that molecules can be excited without at the same time necessarily increasing their translational energy. Thus Taylor-Jones's statement as quoted above should be amended to read "The thermal theory asserts that only the translational energy of the molecules plays a part in ignition", because it cannot be supposed that the ratio between excited and normal molecules in a gas is determined solely and in all circumstances by the temperature.

There are, however, many well-established facts, such as, for example, the photo-ignition of hydrogen-chlorine mixtures, which suggest that internal molecular energy does in fact play a preponderating rôle in ignition and thus appear to contradict the view of the importance assigned by the thermal theory to translational energy. Further, in conjunction with H. H. Thompson[2] I have shown by a crucial experiment that fact and the thermal theory are in direct conflict.

Surface Tension near the Critical Point

IT is well known that when measured values of surface tension are plotted against the temperature a nearly linear law is obtained, but that as a rule the curve is concave upwards and approaches the critical point almost tangentially (even if not quite so) the

surface tension being then zero. It must be borne in mind, however, that this statement is made with respect to the 'measured values'. Those, near the critical point, are usually made by means of the capillary tube method and it is tacitly assumed that if the tube is narrow enough to be considered a 'narrow tube' at ordinary temperatures it will still be so at high temperatures.

The principles of dynamic similitude show, however, that this is not the case. The shape and elevation of the meniscus depend not on the radius r alone but on its relation to β where β^2 (the capillary constant) equals σ/gp. In fact β^2/r^2 = function of h_0/r where h_0 is the capillary rise at the mid-point of the tube. The observed quantities are h_0 and r and from these β^2 must be calculated. Now when β is large compared with r (and therefore h_0 is large compared with r) the tube can be considered as narrow and β^2 can be calculated by a very simple relation. But near the critical point β^2 and h_0 are

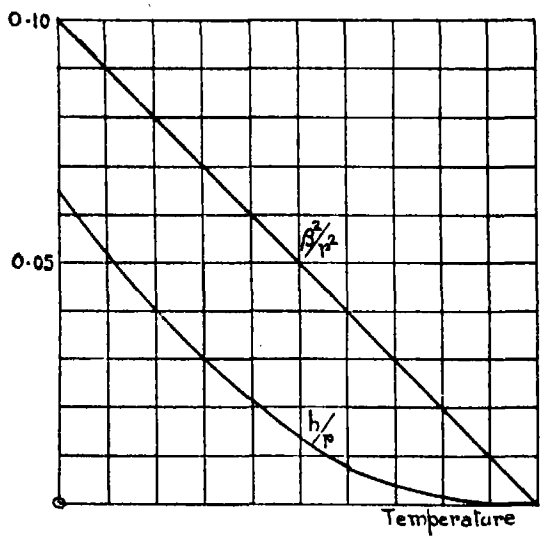

FIG. 1.

very small; the tube now behaves as a very wide one. The functional relation is in such a case much more complicated and it is only since Rayleigh's paper of seventeen years ago[1] that it has become possible to calculate β^2 from the experimental observations.

The most important of these observations were made by Ramsay and his co-workers and published so far back as 1893 in the *Philosophical Transactions of the Royal Society of London*. We may be quite certain, therefore, that the only corrections made were those suitable for a narrow tube. If so, the values which are usually quoted and discussed are really values of $\frac{1}{2}h_0/r$ (or of some quantity very near thereto) and it is to these that the various properties discussed by Baron Eötvös and others relate.

With the help of Rayleigh's equation for very wide tubes it is possible now (and has been for the last seventeen years) to make a proper reduction of the experimental values. This I have done for the special case in which β^2/r^2 is assumed to be a strictly linear function of the temperature. The result is shown in Fig. 1, which is drawn to scale. The values of h_0/r have been calculated from β^2/r^2 (by working backward) and are shown on the lower curve. It will be seen at once that this lower curve *has precisely the characteristics which are usually attributed to* β^2 or rather to the values of surface tension calculated from it.

This suggests that it is quite possible that β^2 is a linear function after all; but it is necessary first to find out (if possible) what were the radii of the tubes actually used by various investigators. This preliminary note is written as a warning to those who, like myself, have spent much time in connexion with this question.

The curve shown has very wide applications. The quantities β^2/r^2 and h_0/r are both pure numbers and a single pair of curves gives the relation between the two sets of values. If, for example, $h_0/r = 0{\cdot}03$ (whether for narrow or wide tubes) then β^2/r^2 at the same temperature has the value 0·07 which is on the same vertical. The *scale* of temperature is adjustable and is therefore not indicated on the diagram. If by altering this scale the experimental values of h_0/r fit the lower curve exactly, then at the same time the values of β^2/r^2 will fit the upper curve. The altered scale need not be simply proportional to the old one; it can be any function of it: but this generalisation need not be further insisted on in this note.

While writing upon surface tension, I may point out that if cream be poured locally on fruit salad and sugar be sprinkled on the exposed parts of the juice, the cream rushes up to meet it; thus showing that the surface tension is increased by adding sugar.

Partial Molecular Polarisations in Solutions

THE dielectric polarisation P_{12} of a mixture of two liquids S_1, S_2 is given by :—

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1 M_1 + c_2 M_2}{d},$$

where ϵ is the dielectric constant, c_1, c_2 the molar fractions and M_1, M_2 the molecular weights of S_1 and S_2, and d the density of the solution. Since this quantity has the dimensions of volume, it would appear that the partial polarisations of the two components should be determined by methods similar to those used in evaluating partial volumes, etc.

It has usually been assumed that in solutions containing polar and non-polar components, the molecular polarisation of the non-polar component can be given a constant value P_1, in which case the polarisation of the other component is given[1] by :

$$P_2 = \frac{P_{12} - c_1 P_1}{c_2} \quad . \quad . \quad . \quad (I)$$

The true value of the partial molecular polarisation $\bar{P}_2 = (\delta P_{12}/\delta n_2)$ may be evaluated by the method of intercepts.[2]

Both methods give the same value for a substance present in small concentrations and also when the $P_{12} - c_2$ curves do not diverge greatly from a straight line. If the curve has a maximum, or a point of inflexion, the values of P_2 and $\bar{P}_2$ calculated in these ways may differ considerably. Fig. 1 shows (1) the experimental $P_{12} - c_2$ curve of solutions of *n*-butyl alcohol in heptane[3], curves (2) and (3) the approximate values of P_2 and $\bar{P}_2$ determined by (I)

and by the method of intercepts; (4) is the constant value of P_1 assumed in calculating P_2 and (5) the values of $\bar{P}_1$ determined by the method of intercepts. In this case the assumption that P_1 can be taken as constant is evidently far from true. It may also

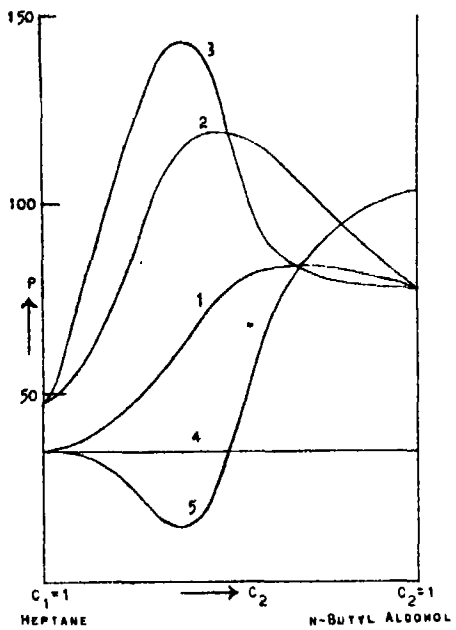

FIG. 1.

be observed that the positions of the maximum of the curves of P_1 and P_2 are considerably different.

Colour Changes in Crustacea

COLOUR changes, in response to light and darkness and to background tint, are well known in prawns and shrimps. I have found this faculty to be present in other decapod Crustacea. It is exhibited by *Porcellana longicornis*, *Eupagurus bernhardus*, young *Galathea strigosa* and *G. dispersa*, and in two cases referred to below.

It has been shown by Hogben and his school[1] that colour change in Amphibia is due to two causes. (1) Light acts directly on chromatophores (primary effect), and (2) light reflected from the surroundings acts through the eyes, causing the liberation of hormones into the blood, which in turn act on the chromatophores (secondary effect). In the Decapods there appears to be a similar dual control of the chromatophores. (1) Primary effect: light, acting directly on the chromatophores, can cause expansion of the pigment, while in the absence of light the pigment is contracted.[2] (2) Secondary effect: light reflected from a light-coloured background acts on the eyes with the result that a hormone, contractin, is liberated into the blood from glands in the eye stalks. This hormone causes pigment contraction in the chromatophores.[3] A black background, through optical stimulation, causes another hormone, expantin, to be liberated from the rostral gland, with resulting pigment expansion.[4]

Experiments which I have made show that hermit crabs also exhibit this dual control of the chromatophores. The responses of *Eupagurus prideauxi* are as follows. (*a*) In darkness the crabs become pale (primary effect). (*b*) On a dark background in light they become dark (secondary effect). (*c*) On a light background in a dull light they become pale (secondary effect). (*d*) On a light background in a bright light they become dark, although not so dark as in (*b*) (balance between primary and secondary effects). Now, the chromatophores on the abdomen and its appendages are functional, although they are concealed within the mollusc shell. When crabs carrying their shells are on a light background in a bright light (*d*, above) the abdominal chromatophores are less expanded than those on the rest of the body. But when such crabs are removed from their shells, light can act directly on the abdominal chromatophores, and within a few minutes they expand as fully as the others.

In the shore crab (*Carcinus mænas*) dark-coloured adult individuals exhibit no colour changes, but light-coloured animals show a small amount of colour response. Most young individuals (1–2 cm. across), however, exhibit colour responses to backgrounds and to darkness within 30 minutes. As the crabs age, this faculty is gradually lost, individuals of 2–4 cm. requiring one or more days to react. In the dark-coloured adults, which do not change colour, most of the chromatophores beneath the carapace are expanded. Blood from these crabs injected into prawns usually causes them to darken, showing that an excess of expantin is present. Now, the removal of the contractin glands in *Crangon* has been found to cause the calcium content of the shell to diminish, suggesting that contractin is concerned with calcium deposition.[5] It is possible that the scarcity or absence of contractin in adult *Carcinus* may be connected with the deposition of salts in the thick exoskeleton. In Amphibia, too, there is a connexion between calcium metabolism and colour change. The pars tuberalis of the pituitary is concerned with the colour response of these animals to white background.[1] Now, a fall in blood calcium following pituitary removal occurs in Amphibia,[6] and in a private communication Prof. Hogben writes that Dr. Zwarenstein, working in his laboratory, has recently proved this fall in calcium to be due to the removal of the pars tuberalis.

Research Items

The Severn Crossing in Roman Times.—During the course of the present year Dr. C. Scott Garrett and Mr. Frank H. Harris, 23 Newerne St., Lydney, Glos., have discovered the foundations of extensive Roman buildings in three fields known as the 'Chesters' on the land between the Severn and Woolaston Pill. In a communication sent to NATURE they suggest that this gives ground for a revision of the current idea that the Roman station of Abone was Sea Mills on the Avon. This identification is supported by Haverfield, Collingwood and the Ordnance Survey map of Roman Britain. It must be remembered that the water level of the Severn was considerably higher in Roman times than it is now, and even to-day the low land behind Caerwent is sometimes flooded, so that the station itself must have been very near to the water when it was built: of this there is abundant archæological evidence. On the other hand, the erosion on the right bank of the river has been so extensive that only half of Sudbrook camp remains. But this loss has been more than compensated for by the deposition of alluvium on the left bank. Supposing that the Severn once flowed not far from the foot of Shirehampton Hills, then the Roman port was probably either at Sea Mills or on the Severn just to the east of it because the Roman road from Bath to Bitton and on to the north crossed Durdham Downs in the direction of Sea Mills, and if the point of departure had been elsewhere, for example, at Oldbury, it would have been as easy for the road from Bath to go there direct as via the Avon. A road from Sea Mills to Gloucester is marked on the ordnance map, but this would have been an indirect approach to Oldbury, unlike the usual Roman method of road planning. It has long been known that there was a Roman station at Sea Mills, and when the Portway, the new low level road along the Avon was cut, a few years ago, a great deal more Roman material, including the foundations of buildings, was discovered. On the whole, this site fits well into the position of Abone given in the itinerary of Antonine, though the problem of "Trajectus" has been variously solved by scholars. However, no more distant site would meet the requirements of the twenty-four miles allowed between Bath and Caerwent.

The Wynad.—In "Notes on the Cultural Geography of the Wynad" (*Indian Antiquary*, Sept., Oct., 1932), Mr. F. J. Richards reviews the history and ethnology of the Wynad, which forms the southern bastion of the Deccan plateau. The plateau is hemmed in by the Coorg Hills on the north and the Nilgiris on the south. By its natural features the country is divided up into areas which differ from one another in their cultural affinities. On the Malabar borders it is densely forested, while on the Mysore border is a broad deciduous bamboo belt. An area of about 1,100 sq. miles supports a population of a little more than 100,000. The Wynad has never been studied intensively from the anthropological point of view. Before the introduction of tea and coffee planting, the population was mostly confined to swampy ground along the river valleys, growing paddy. They had no use for the forest land, all the pasture required being provided by the low hillocks which grow from the swamps. Each river valley supported a more or less homogeneous community. The oldest stratum in the population is, presumably, the curly-headed Paniyar, speaking corrupt Malayâlam, whose method of fire-making by 'sawing' links them with the jungle folk of Malaya. The Ten Kurumbars and Shola Nâyaks are more purely jungle folk, speaking Kanarese. The Kurrichans are the highest in social standing of all the tribes. They cultivate their own lands and are keen fighters and hunters. The evidence of language and tradition pointing to Malabar influence is supported by the 'forelock' in the style of hair-dressing and by the dress. The land-tenure is also modelled on Malabar. The Wynad religious cults are clearly imposed on something older. The area abounds in evidence of an earlier populous civilisation, historic and 'prehistoric'. The present depopulation may be due to the malaria of the bamboo belt.

Madras Plankton.—In a preliminary account of the plankton of Madras, K. S. Menon (*Rec. Indian Mus.*, vol. 33, pt. 4, 1931) gives a list of the principal organisms met with. He states that while a few genera, for example, *Sagitta* and *Pleurobrachia*, show little variation in numbers throughout the year, most of the organisms in the plankton exhibit periods of maxima and minima. This seasonal variation is not so clear-cut as in the European records; for example, many of the copepods have a definite maximal period but are scarcely ever absent. This is probably because the weather conditions and changes in the constitution of the sea-water vary less than in colder seas. The plankton of the west coast of India, as recorded by Hornell and Naidu, shows great scarcity of diatoms in December, a secondary maximum in January and February, a fall in March and the principal maximum in May. In the Madras plankton, diatoms are scarce in August and September; the secondary maximum is from November to January and is made up mainly of *Coscinodiscus*. The true phytoplankton maximum is in May; diatoms become fewer in June but in July reappear in large numbers and then disappear rapidly. There is no separate dinoflagellate maximum; it coincides with the diatom maximum in May. The copepod maximum is from November to February inclusive; the difference between this and the condition in European seas is the inhibiting factor of cold in the latter.

Primitive Conducting Mechanisms of the Vertebrate Heart.—Employing as research material larval *Lepidosiren paradoxa*, Dr. Tudor Jones has published an important paper on this subject (*Trans. Roy. Soc. Edin.*, vol. 57, 1932). He has shown that all the conducting mechanisms hitherto described are here represented by purely nervous structures, and that their appearance preceded the general development of cardiac muscular striation. The entire system has been traced out and shown to consist of a nervous continuum consisting of two regions of the medulla oblongata, intermedio-lateral and ventral, with communications involving the sixth aortic arch, the ductus Botalli, the pulmonary artery, the sinus venosus, atria and ventricles of the heart, and, finally, the pulmonary vein. There are also bilateral communications at three levels which are probably of segmental origin. These structures form, at the cardiac end, a nervous complex to which, Dr. Jones

believes, the whole development of the heart may be referred "as to an organic system of developmental foci". It is of great interest to learn that structures, such as the sixth aortic arch, the ductus Botalli, the pulmonary artery and the heart, which were not previously known to be related, are actually so related by their fundamental *innervation*.

Biochemistry of Sea Life.—In a paper, compiled for a symposium at the Pasadena meeting of the American Association ("Life in the Ocean from a Biochemical Point of View". *J. Washington Acad. Sci.*, **22** (9), 246–257, 1932), Paul S. Galtsoff deals with the importance of certain minor constituents of sea water for plant growth and tabulates the concentrations of the elements in the sea, so far as they are known, also the ratio of the concentration in tissues to that in sea water. The high concentration of zinc in tissues, up to 10,000 times the amount in sea water, is noteworthy. Mention is also made of Prytherch's work upon the effect of traces of copper in river water in stimulating oyster larvæ to become attached. Interesting temperature effects have also been quoted. The paper might profitably be read by all interested in marine life.

Biological Significance of Colloidal Structure.—The structure of the protein is considered very suggestively from the biological point of view by Dr. D. Jordan Lloyd in *Biological Reviews*, vol. 7, No. 3, July, 1932. The high content of water in actively growing protoplasm is emphasised. This water is a necessity if the metabolic reactions associated with vital activity are to proceed in solution and it is pointed out that the proteins in the living protoplasm probably have highly hydrated polar amino-acids linked to the CH–NH–CO backbone, which itself supplies an element of stability to the structure. The water relation of such a protein system would be highly sensitive to changes in environment. On the other hand, in both plant and animal tissues, fibrous structures are present, constructed of protein in the animal and of carbohydrate in the plant, which are essentially stable and have a low water content. In these fibres the stable backbone of the long-chain chemical structure, which is itself little hydrated, has linked to it comparatively few polar side chains with strong affinity for water, but it is built up of a series of stable ring linkages following one another with periodic regularity, so that X-ray analysis can be employed to unravel their structure. Such structures combine stability and resistance to decay with a low water content and slight affinity for water. Thus from the same colloidal systems structures may be built meeting the very diverse needs of living organisms.

A Disease of Dahlias.—A leaf-spotting disease of dahlias occurred at Wisley in 1930. It was studied in detail by Mr. D. E. Green, who now reports the results of his investigations (*J. Roy. Hort. Soc.*, vol. 57, pt. 2, pp. 332–339). Detailed descriptions of the symptoms are given, and the causal fungus has been identified as *Entyloma dahliæ*, Sydow. Various control measures have been tried, and some success has attended the use of Bordeaux mixture used as a spray in August. French growers state that late planting aggravates the disease. No satisfactory demonstration of the way in which infection spreads in the field has been given, and preliminary experiments on direct infection with spores have not produced the disease. Further work is in progress to try to find how the fungus overwinters.

Dipterocarpaceæ of the Malay Peninsula.—From a commercial forestry point of view, the group of Dipterocarpaceæ contains some important timber trees, and yet the knowledge of them so far attained is said to be very incomplete. Mr. H. N. Parker has been studying the Indian and Burman species at the Forest Research Institute, Dehra Dun, and Dr. F. W. Foxworthy, the forestry research officer of the Federated Malay States, has been undertaking investigations in the group in the Malay region, where it forms so important a portion of the forest flora. This work appears in *Malayan Forest Records* (No. 10, Singapore, pp. 289, plates 33 and map, 1932). Dr. Foxworthy states that the knowledge of the group remains very incomplete, in spite of the fact that it contains the most important group of timber trees of the Malay States. Attention has often been directed to the difficulty of obtaining herbarium material because of the very large size of the trees, the scarcity of population in the forests, and the relatively infrequent flowering and fruiting of many species. There have been but few botanists specialising in the group, and collections, until recent years, have been few. The author has worked at the group for a number of years and has had the opportunity of examining types and critical material in the herbaria of Leyden, Kew, Calcutta, Singapore, Buitenzorg and Manila. Dr. Foxworthy's untiring labours have added very considerably to our knowledge of the Dipterocarpaceæ.

Solar Influence on Cosmic Radiation.—The Bauer memorial number which constitutes the September issue of *Terrestrial Magnetism and Atmospheric Electricity* contains a short contribution by Prof. Hess of Innsbruck describing the cosmic radiation observatory he has set up on the Hafelekar at a height of 2,300 metres above sea-level. The apparatus is of the same type as that in use at the other observatories which are taking part in the co-operative plan of work organised by Prof. Hess, a list of which was given in a note in NATURE of November 26, p. 816. The ionisation chamber contains 22 litres of carbon dioxide at 9·5 atmospheres and the ionisation current to the electrometer is compensated as in Hoffmann's apparatus. The records are taken photographically and from September last year until May this year they show that the ionisation during the day is about 0·2 per cent greater than during the night.

Mechanism of Gaseous Explosion.—The November issue of the *Proceedings of the Royal Society* contains two papers on the mechanism of explosive oxidation in the gas phase. One by Hadman, Thompson and Hinshelwood describes experiments on dry carbon monoxide in silica vessels at temperatures around 700°. There is an upper and a lower limit to the pressure range over which explosion takes place, and the reaction goes on slowly outside these limits. The lower limit does not depend markedly on the temperature; its dependence on the size of the reaction vessel is apparently masked by other differences in the

vessels. It is lowered by the presence of inert gases. The upper limit rises rapidly with temperature. A peculiar effect was obtained when the pressure of a mixture was gradually lowered until it was well inside the reaction limits without explosion taking place. This is said to be due to a 'poisoning' of the walls of the vessel by carbon monoxide. The results are explained on the basis of a reaction which starts at the surface of the vessel and proceeds by a chain of reactions. The lower limit is then determined by the diffusion of active centres to the wall of the vessel and is lowered by inert gases which diminish this diffusion. The upper limit is determined by a de-activation process taking place in the gas phase. The second paper, by Hinshelwood and Moelwyn-Hughes, deals with the hydrogen-oxygen reaction in silica vessels, and describes experiments on the lower limit of pressure for explosive reaction. As with carbon monoxide, inert gases lower this limit, and here there is rough quantitative agreement with the assumption that the inert gas prevents the loss of active centres by diffusion to the wall.

Short Wave Radio Propagation.—In view of the increasing use of short waves for radio communication, any new facts concerning them are of great interest to engineers. In a paper read before the Institution of Electrical Engineers on December 7, Prof. J. Hollingworth gave experimental data obtained by examining signals with a cathode ray direction finder, received at distances up to 7,000 miles, having frequencies of the order of 10,000 kilocycles a second. The work carried out is part of the programme of the Radio Research Board. The two outstanding features noted in the research are the systematic appearance of certain cyclic forms on the end of the tube of the direction finder and the large values obtained for the horizontally polarised electric components. An ellipse, which is generally in a violent state of oscillation, is seen in the tube. This shows that there is an abnormally polarised wave present. 'Fading' gives a change in the size of the ellipse without change of shape. An analysis of the ellipse forms is given based on Appleton's magneto-ionic theory. This theory predicts that in general each up-going ray will be split into two elliptically polarised components with opposite directions of rotation, which recombine on emergence from a layer where they have suffered differential phase change and absorption. The author concludes from the evidence that in general the magneto-ionic theory seems to provide a reasonable explanation of the majority of the observed phenomena. The experiments were originally undertaken in a spirit of pure inquiry but some of the results are so surprising that they inevitably challenge accepted ideas.

Astronomical Topics

The Leonids.—The fullest series of observations yet to hand was made by Dr. V. Guth at Stary Smokovec in Czechoslovakia (height 1,020 metres). He gives in U.A.I. Circular No. 408 the following table of his observations :

U.T.	Nov. 16	Nov. 17	Nov. 18	Nov. 19	Nov. 20
0^h–1^h	16	*cl.*	*cl.*	*cl.*	*cl.*
1-2	42	*cl.*	*cl.*	*cl.*	3
2-3	40	*cl.*	*cl.*	0	5
3-4	57	*cl.*	*cl.*	6	*cl.*
4-5	63	*cl.*	5	3	3

cl. means cloudy or misty.

On the first night there were 15 meteors brighter than mag. 0. One that was seen at 3^h36^m on that night was a detonating meteor, mag. – 5. The above figures suggest that maximum may have occurred during daylight on November 16, which would accord with prediction.

Mr. M. A. R. Khan made the following observations of Leonids at Hyderabad : Nov. 8, 11 in 60^m ; Nov. 9, 5 in 30^m ; Nov. 11, 10 in 60^m ; Nov. 12, 9 in 80^m ; Nov. 13, 2 in 30^m ; Nov. 14, 7 in 60^m ; Nov. 16, 20 in 70^m. Two meteors on Nov. 8, and four on Nov. 16, were noted as bright. The observations were made between 20^h and $23\frac{3}{4}^h$ U.T. on the days named. The nights of Nov. 10, 15, and 17 were cloudy throughout.

Planetary Perturbations.—Prof. W. H. Pickering, in an article in *Popular Astronomy* for November, criticises a paper by Prof. E. W. Brown (*Mon. Not. Roy. Ast. Soc.*, vol. 92, p. 80) in which the statement occurs "From time to time statements have been published . . . that the maximum observable effect of one planet on another will take place at or close to conjunction. How completely erroneous such statements are can be shown . . ." Prof. Pickering distinguishes between the largest perturbations and those of sharpest curvature. He admits that the former take place when the planets are on opposite sides of the sun ; but the wave produced by them is so long that in the case of a planet that has only completed one revolution since discovery they cannot be separated from errors in assumed eccentricity and perihelion point. Those that occur near conjunction of the planets, though smaller, are easier to distinguish from errors of the elements, owing to their more rapid change. Prof. Pickering appears to justify this assertion by recalling the circumstances of the discovery of Neptune. Bouvard, in his tables of Uranus published in 1821 (the year of its conjunction with Neptune), rejected all the observations of Uranus made before its discovery in 1781 ; nevertheless, his tables soon began to exhibit appreciable errors. These were prominently shown in the Cambridge observations of 1828 ; in 1834, the Rev. T. J. Hussey wrote to Airy suggesting the existence of an exterior planet, and offering to search for it if an approximate position could be given. Bouvard himself had the same idea in 1837. Airy admitted in that year that the "errors of longitude are increasing with fearful rapidity", though he had not much confidence that the position of the unknown could be determined ; he said, however, that the facts "tended greatly to impress upon astronomers the absolute necessity of seeking some external cause of disturbance". Prof. Pickering's deduction that an observable effect does occur about the time of conjunction appears justified. It is well known that he tried to deduce from the observations of Neptune the position of an external planet ; he made three different determinations of its position, which were published in 1909, 1919 and 1928 ; the middle one was within 69′ of the true place of Pluto at the time of publication, the others were some 27° away from it. In fact, Pluto was photographed at Mount Wilson in 1919 as a result of that prediction, but the images were not detected until 1930.

The Discovery of Peking Man*

IN his Croonian lecture on *Sinanthropus* or Peking man, Prof. Davidson Black gave a full and detailed account of the circumstances leading up to the discovery of the skeletal and cultural relics of this primitive human type and of the conditions, geological and other, in which they were found.

The first indication of the presence of early man to be found on the site was in 1921 when Dr. J. C. Anderssen, then mining adviser to the Chinese Government, noticed fragments of white quartz among loose talus at the foot of fossiliferous deposits exposed in the south wall of a disused quarry in the Ordovician limestones at Choukoutien. As no quartz of any kind occurs naturally in this part of the Choukoutien area, he at once inferred the presence of primitive man. From this point Prof. Black described the investigations which led to the discovery of a fossil tooth, first announced in 1926 on a report from Uppsala, where material from Choukoutien was under investigation; the discovery of the fossil tooth by Dr. Böhlin in 1927, upon which was based the recognition of a new human genus, *Sinanthropus*; and the discovery of the first and second of the two skulls in 1929 and 1930 by Dr. W. C. Pei, under the Cenozoic Research Laboratory, which was organised by the Geological Survey of China in 1929 and now functions as an integral part of that service. In 1930 the Geological Survey acquired by purchase full title to the *Sinanthropus* site, which is thus preserved to science for all time.

In 1931 Dr. Pei discovered artifacts and evidence of Peking man's use of fire in an undisturbed fire-blackened stratum. Prof. Black also referred to the other skeletal fragments recently described, as well as to six lower jaw fragments, of which an account is to appear shortly. The endocranial cast which has been prepared indicates that *Sinanthropus* was right-handed and possessed a nervous mechanism for the elaboration of articulate speech.

In his account of the conditions of the discovery Prof. Black was on what was probably to most of his audience less familiar ground. Channels and caverns have been hollowed out of the Ordovician limestone by the solution action of ground water; and after the elevation of the formation, erosion removed the overlying strata. Fissures which formed have been filled and these deposits converted into travertine.

The cavern occupied by *Sinanthropus* was large, of irregular shape, and opened towards the river valley to the east. Throughout the time it was being gradually filled by detritus, it was wholly or in part occupied by *Sinanthropus*. His occupation must have extended over hundreds, probably thousands, of years, for more than thirty metres of undisturbed strata remain, showing evidence of his presence throughout. During the later part of his occupation the fauna did not change, but remained typically that of the upper part of the Lower Pleistocene.

Most of the northern limestone wall limiting the original cave has been removed by modern quarrying operations exposing the solidified detritus. Up to 1932, excavations of the actual deposits have been confined to the regions accessible from the northern face. Work is now progressing along the line of contact between the accumulated deposit and the southern wall of the original cave.

The modern cave of Kotzetang is really the result of recent excavation, made probably by quarrymen, in the relatively unconsolidated portion of the great stratified breccia comprising the eastern portion of the main Choukoutien deposit. The northern wall is part of the original northern wall of the cavern.

Prof. Black also referred to the artifacts and the recent study of them by Dr. W. C. Pei and P. Teilhard de Chardin, from which it is concluded that *Sinanthropus*, "culturally speaking, is to be considered as an early representative of the Old Palæolithic cycle, but his craft displays a crudity which indicates that he but obeyed and never mastered the materials with which he worked".

* Substance of the Croonian lecture delivered by Prof. Davidson Black before the Royal Society on December 8.

Capacitance Hygroscopy and some of its Applications

By Dr. W. LAWRENCE BALLS, F.R.S.

SOME experiments were briefly noted in this journal last April[1] whereby the high dielectric constant of water was used to indicate variations in the water-content of substances contiguous to a leaky condenser, by means of a resonance method. It would seem that other workers are exploring the same track, with the difference that they draw samples which are placed in special condenser-containers for measurement, whereas I prefer to take full advantage of the method in evading the ubiquitous 'sampling-error' so far as possible; even at the sacrifice of some accuracy in the actual determination. Great accuracy is probably unobtainable in any case; the dielectric constant even of free water is not a constant, but the margin of difference between water around 80 and most other common substances below 8 is large enough for most classes of comparative work.

The necessary apparatus is as portable as an attaché case, and is proving itself to be of versatile utility. Examples will shortly be given. On the analogy of resistance thermometry, I suggest that the general technique might be termed 'capacitance hygroscopy'.

The arrangement at present used is necessarily capable of improvement in electrical design, but it functions very usefully when its limitations are respected, especially since the discovery of papers by Lattey and his collaborators has allowed voltage-tuning to be incorporated.[2] This is done by applying the resonator voltage to the grid of a second valve, the anode current of which then indicates the voltage, as in the Moullin thermionic voltmeter[3]; the coupling between the generator and resonator can be kept very loose, and a feeble and portable generator used with safety. The triple circuit shown in Fig. 1 is also a plan of the arrangement. It undergoes small zero shifts due to temperature and also to earth-capacity, but these are eliminated by zero-setting with one variable condenser, prior to measurement on the

other one. Variations of resistance in the unknown capacity can also alter the 'capacitance' readings, in spite of voltage tuning, as Lattey has recently pointed out; the elimination of these errors is no doubt possible, but even now it is practicable to obtain accurately comparative readings in repetition work, the voltage indications serving as a warning of abnormal conditions. Definite fixation of frequency by a quartz crystal, capacity coupling, and proper screening, are obvious improvements next to be made.

Three examples of very diverse applications will now be outlined.

SOIL-WATER DETERMINATIONS

The buried condensers are, as formerly described, made from purchased glass web-tube, or from home-made capillary web-tube produced by blowing two bulbs together and then drawing them out. Staybrite steel wire (33 s.w.g.) is used for the final lead-in, to avoid amalgamation. Gutta-percha seals these wires in the entrance to the web-tube. The larger tubes are wrapped in a thin skin of cotton fabric dipped in plaster of Paris, so as to stabilise the capillary water conditions in contact with the glass; an assumption is made here. The leads are made of thin widely-spaced wires inside gas-pipe, so that they may be as insensitive as possible to the soil-water variations until the web-tube is reached at depths of three metres or so, but their design is not yet properly worked out.

Some very complex curves for changes in soil-capacity with changes of moisture have recently been published,[4] determined by a compensated bridge method. They contrast very sharply with such simple curves as Fig. 2, which seem to me to be more inherently probable. Actually even these latter

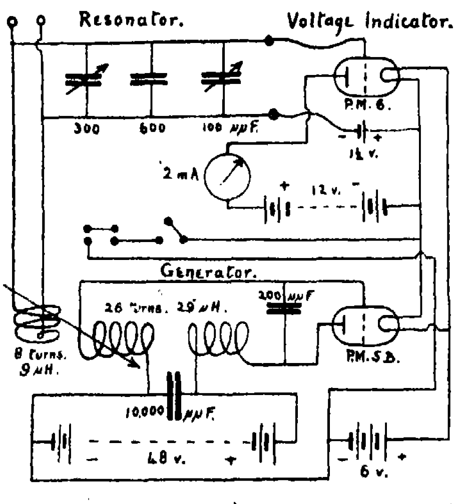

FIG. 1—Circuit diagram and plan. $\lambda = 150$ m.; $f = 2000$ kc.; $\delta = 0{\cdot}06$. Size: 12 cm. × 32 cm. × 38 cm. Weight 8 kgm.

are more complex than those obtainable in deep soil, because the capillary web-tube condensers were buried initially in air-dry soil which was allowed to swell freely on saturation with water, and then to shrink into a compact block as it dried. In the field one would not obtain the volume increase except near the surface. The inflection shown by both curves, representing two separate experiments, near the point at which deep soil becomes water-logged in the field,[5] marks the upper limit of capacitance under deep soil conditions. The fragment of hysteresis loop obtained after oven-drying and slowly damping again by exposure to air, is probably also abnormal in width, owing to minute air-space cracks developing between the soil and the bare capillary glass.

TESTING COTTON BALES

As president of the Trustees of the new Alexandria Testing House, founded in consequence of an international trade agreement. I have been given exceptional facilities by the pressing firms of Alexandria,

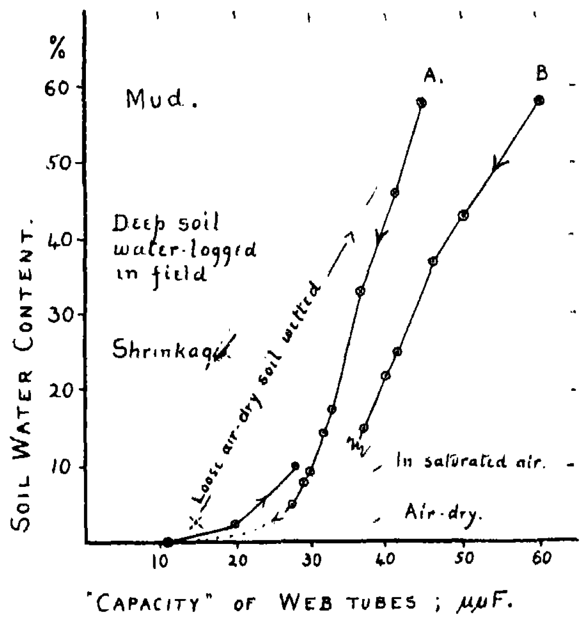

FIG. 2. Soil moisture.

to obtain data from bales specially prepared to various moisture contents, while Mr. D. A. Newby has collaborated in making the oven tests more exact. Capacitance tests are now being taken as routine on the hoops of all bales from which oven-tests are to be made, so as to accumulate several hundred pairs of observations. It already seems likely that so long as the test is limited to freshly pressed and homogeneous bales, as formerly suggested, we have a useful and rapid method of control which can test every bale made, and can do so at much less cost than the usual oven-testing of every tenth bale. Whether it can be trusted to the extent of dispensing with oven-tests at the press-foot remains to be seen.

I excluded the non-homogeneous bale from the original scheme of possible capacitance tests, but the finding of a solution for the special problems created by the presence of a wet or dry outer layer, or even more complex distributions of water in depth, is most alluring. It now appears that differential testing at various depths can be done by altering the grouping of the bale hoops upon which contact is made when the attaché case is hung on the bale. Fig. 3 shows how the drying of the surface during hot dry summer weather, from one day to another, is much more noticeable when successive hoops are 'contacted' (2,4,6 v. 3,5) than when deeper penetration of the field of force is secured by missing out three intervening hoops (2.10 v. 6). Such a figure is also a

nomograph for determining moisture content. The case is analogous to resistance measurements in geophysics, but the curve of penetration seems unfortunately to be much flatter.

An incidental fact is that the 'capacitance' observed by our system of using the bale-hoops themselves as condenser 'plates' is almost exactly proportional to the volume of the triple dielectric—air, cotton, water—and not to its thickness. A similar departure from convention is shown by the capacitance of 'hoops in air', namely, a bale-skeleton of hoops spaced out on thin wooden rods: the capacitance of a few wide-spaced hoops is markedly higher than it should be in relation to the reading from close-spaced hoops.

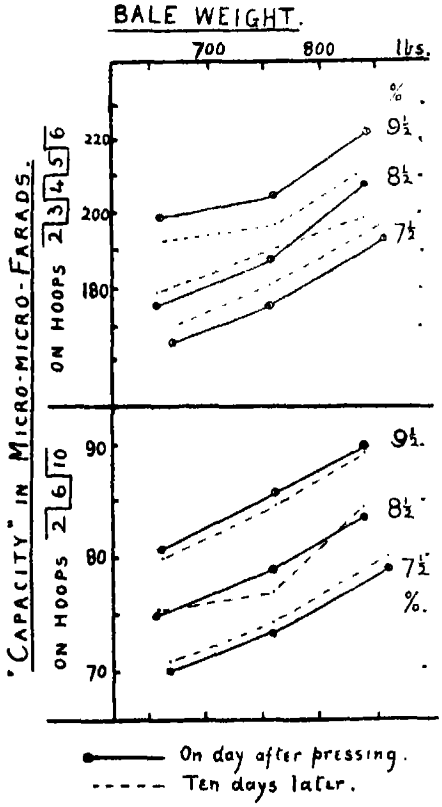

FIG. 3. Cotton bales.

A trial of the method at Manchester Docks on a day when the weather was typical for the locality, using a hoop-grouping which tested only the surface of the bale, gave the interesting result that the surface moisture content was so high as to be off-scale, although the average of the whole bale when oven-tested was near normal. The bale had gained two pounds in weight since being taken off the ship. The demonstration was a failure from the spinner's view-point, but very successful from the exporters'.

INDICATING THE GROWTH OF CROPS

It is common experience that the capacity of a radio antenna is increased by the increasing proximity of branches of trees, but we are not aware that the phenomenon has been used in the inverse direction, to measure the growth of the tree.

Some small scale experiments in my English garden, made chiefly on the exceptionally difficult subject provided by a grass lawn, show that the capacitance hygrometer apparatus is usable to give instantaneous readings of the changes in capacitance consequent on increased water-content due to enlargement by growth. Two forms of 'condenser' have been used, the first being bare wire netting half a metre square, supported on insulation at 5 cm. above the surface of the lawn, with a counterpoise earth of similar netting below it, pegged down firmly; the grass and clover grew through this lower plate of the condenser, the capacity of which rose as shown in Fig. 4, evidently following the varied weather of the period, and the final removal of one-fifth of the grass with a hot iron.

Such arrangements of bare wire suffer from instability, on account of defective insulation, especially when water-drops are present after rain or dew. This is more easily examined by using miniature antennæ of wires stretched under constant tension. If rubber-covered wires are used, including a counterpoise wire, the 'capacity' observed is inversely as the voltage, due to dielectric absorption.

A workable arrangement consists of three such wires, each 3 metres long. One is pegged firmly down to the surface of the freshly mown lawn as a counterpoise, the other two supported above and parallel, forming an equilateral triangle in end view, of 3 cm. side. The field of force between the two upper wires on one hand, and the counterpoise on the other, passes through the growing grass; the initial capacity is about 100 μμF., and may rise as much as seven or eight μμF. in a day. From this starting point we can design longer and more widely spaced antennæ, and it should be a simple matter to string such antennæ across a field of growing crops; the reading could be made continuous by coupling my universal recorder to the condenser dial and operating it by a contact on the milliammeter; the decrement of the circuit as well as the capacity would thus be recorded. The method seems eminently suited to cereal crops, which have hitherto presented serious difficulties in growth-measurement. As before, the sampling error becomes trivial.

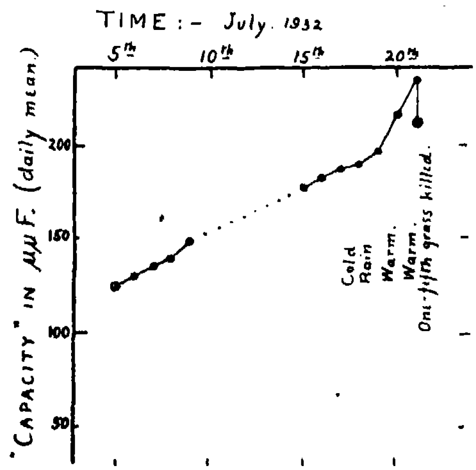

FIG. 4—Condenser of wire-netting on a grass lawn.

In all such arrangements it is evident that the capacitance increment for a given volume of growth will change progressively, so that it would be difficult to establish a quantitative relation over long intervals of time. But this is relatively unimportant, since long-period growth is obtainable by cruder methods;

the discrimination between growth-rates on successive days is easy, and this has been the difficult part of field-growth measurement.

An extensive publication of the results obtained in the many thousands of readings which have been taken by this method during the past year does not seem justifiable, since so many of them have been devoted to elucidating electrical difficulties which could probably have been solved *a priori* by a more competent worker. Some detailed publication on the special case of the cotton bale will in any case be necessary, on account of its commercial importance. On the other hand, it is clear, from letters received, that the application to soil alone is of interest to an unexpected variety of scientific students. Therefore it seemed desirable to put together an outline of all the essential facts, difficulties and limitations thus far encountered, so that other workers may be able to develop the application of the technique to their own special problem, and yet may realise that such application is in itself an experimental investigation of the technique and of its many side-issues. The method is qualitative rather than quantitative, and is best used under standardised conditions, until such time as it is more fully worked out; meanwhile, advice and independent effort in so doing would be welcomed.

University and Educational Intelligence

BIRMINGHAM.—At a meeting of the Council on December 7 the Pro-Chancellor (Sir Gilbert Barling) announced a generous gift by Lady Barber, widow of Sir Henry Barber, founder of the Faculty of Law in the University. The benefaction consists of securities providing an annual income of about £12,000, to be devoted "to the provision of an Institute of Fine Arts in the University; to the advancement of music and musical education in the University, and to further developments in the Faculty of Law which was brought into existence by the founding of the Barber Chair of Law". The deed of trust provides for the erection of a building on the University site at Edgbaston to include galleries for exhibition of works of art, a chamber for musical recitals, and a musical department with a library and a museum for the accumulation of musical manuscripts.

The Pro-Chancellor, Sir Gilbert Barling, has announced his intention of retiring from office at the end of the year. Sir Gilbert Barling, who succeeded the first Vice-Chancellor (Alderman C. G. Beale) in 1913, has an extraordinary record of personal service to the University, in which, at the age of seventy-seven years, he still takes a very active interest.

A grant of £50 has been made from the Lapworth Research Fund to cover the cost of cataloguing pamphlets, maps, etc., of the late Prof. Lapworth for the Lapworth Library of the Department of Geology.

LONDON.—The Mercers' Company and the Fishmongers' Company have decided to make grants to the University in the shape of annual payments extending over a series of years and amounting in each case to a total of £10,000. These gifts will be applied by the University towards meeting the cost of the new Ceremonial Hall to be erected on the University's site in Bloomsbury.

THE Institution of Naval Architects scholarship, valued at £130 a year for three years, will be offered for competition in 1933. This scholarship is open to apprentices under the age of twenty-three years, from the royal dockyards or private shipyards, and is tenable at the Royal Naval College, Greenwich, or the Universities of Glasgow, Durham (Armstrong College) or Liverpool. Full particulars may be obtained from the Secretary of the Institution of Naval Architects, 2 Adam Street, Adelphi, London, W.C.2.

THE twenty-first annual Conference of Educational Associations will be held at University College, Gower Street, London, W.C.1, on January 2–9, under the presidency of the Right Hon. the Earl of Athlone. On January 2 there will be a joint conference on "The Trend of Education" at which Mr. H. Ramsbotham, Parliamentary Secretary to the Board of Education, Miss W. Mercier, principal of Whitelands College, and Mr. J. E. Barton, president of the Association of Head Masters, will speak.

Calendar of Geographical Exploration

Dec. 21, 1605.—Torres Strait

Pedro Fernandez de Quiros, accompanied by Luis Vaez de Torres in a second ship, left Callao. Quiros, while pilot on a previous expedition to the Santa Cruz group, had become fired with the idea of a great southern continent, thought by him to lie near Santa Cruz. Quiros passed through the centre of the Low Archipelago, thence north of Samoa and the Fiji group and finally discovered Espiritu Santo in the New Hebrides. Quiros then returned, but Torres continued, discovered the strait named after him and proved the insularity of New Guinea. His discoveries passed unheeded at the time, but after the capture of Manila in 1762, his narrative fell into the hands of Alexander Dalrymple and the value of his work was realised.

Dec. 21, 1835.—Exploration of Oman

Lieuts. Wellsted and Whitelock reached the fertile district south of Jabal Akhdar, the main range of Oman. There they were astonished to see "verdant fields of grain and sugar cane . . . and streams flowing in every direction". Wellsted was the first to explore this south-eastern corner of Arabia scientifically and was, for part of the time, assisted by Whitelock. Political disturbances prevented Wellsted from crossing the desert to Nejd and he returned to India in 1836.

Dec. 23, 1558.—An English Trader in Russia

Anthony Jenkinson reached Bukhara. He was a trader who had travelled in the Levant and went to Russia in 1557. There he set out from Moscow, reached the Volga and sailed down it to the Caspian, making a rough survey of the north of that sea. Thence he travelled to Bukhara, where he spent three and a half months, returning to England through Russia. In 1561 he went to that country again and, following a route along the west of the Caspian, reached Kazvin, the capital of Persia, in October 1562. Though his journeys did much to increase our knowledge of Russia, and the lands to the south-east of it, English trade via that route ceased in 1581, thus giving an impetus to voyages in the Levant.

Societies and Academies

LONDON

Geological Society, Nov. 23.—**A. E. Mourant**: The geology of eastern Jersey. The area described includes the whole of the Jersey volcanic series and certain associated rocks. The oldest formation in the island is the Pre-Cambrian shale series, consisting of grey mudstones and shaly grits. This is succeeded, with a slight unconformity, by the volcanic series, the field relations and petrographic characters of which are described. The volcanic rocks of northern Brittany differ in some respects from those of Jersey. Reasons are given for regarding the Jersey volcanic rocks as Pre-Cambrian. The field relations of the plutonic rocks of the area are discussed.—**E. Willbourn and F. T. Ingham**: The geology of the Scheelite mine, Kramat Pulai Tin Limited, Kinta, Federated Malay States. There are a number of occurrences of scheelite ore at Kramat Pulai, one of them of considerable dimensions, and the ore is of unusual character, being a coarse-grained intergrowth of fluorite and scheelite, with less than one per cent of other minerals. The granite which built up the great main range of the Malay Peninsula was the source of the ore, as it was also of the rich tin deposits that are worked there. Kramat Pulai is situated on the contact zone between the huge plutonic mass and the limestone into which it is intruded. The limestone was converted to marble by the intense folding and thermal action that accompanied the intrusion, and an interstratified bed of shale and silt was metamorphosed to pyroxene-schist and biotite-schist. Gently pitching anticlinal structures were imposed upon the metamorphosed rocks, and minor faults at right angles to them were occupied by aplite dykes. Re-opening of the fissures brought in pegmatitic material, permitted solutions rich in tungsten fluoride to have access to the limestone below the schist-bed, forming crystalline intergrowth of scheelite and fluorite. All the scheelite-fluorite ore is of identically course texture, whether it occurs in a large mass more than 100 feet across, or in a thin vein, 1 inch thick, of secondary origin. The temperature of formation of such thin veins must have been low.

CAPE TOWN

Royal Society of South Africa, Sept. 22.—**J. Groves and E. L. Stephens**: New and noteworthy South African Charophyta (2). Descriptions and figures are given of nine new species, also figures of *N. plumosa* and *C. stachymorpha*, and a revision of the species which Braun included under *C. Kraussi* and *C. phæochiton*.—**E. D. Loseby**: Repeated conjugation in *Closterium pritchardianum*, Arch. Conjugation, following immediately on a period of rapid cell-division, occurred three times within a period of two months in a culture of this species. Each period of active reproduction lasted for about ten days, and there was a fortnight of quiescence between. During the period of quiescence the species was represented by undersized cells, and recurrences of active reproduction occurred when they had reached mature size. —**M. R. Levyns**: A revision of *Lobostemon*, Lehm., and a discussion on the species problem In the revision of *Lobostemon* it has been necessary to separate a small section as a new genus *Echiostachys*. *Lobostemon* is divided into five natural groups characterised by well-marked floral characters. Vegetative characters are very variable. Twenty-eight species of *Lobostemon* and three species of *Echiostachys* are described.—**A. Zoond**: The mechanism of projection of the chameleon's tongue. Experiments are described dealing with the muscles of the tongue and the hyoid apparatus, and with the lingual nerves, arteries and veins.—**H. A. Shapiro and L. P. Bosman**: Note on the skin-secreting mechanism of *Xenopus lævis*. The findings of Hogben, Charles and Slome that removal of both lobes of the pituitary in *Xenopus* leads to a cessation of skin secretion in response to mechanical stimulation, are confirmed. This phenomenon as a result of anterior lobe removal takes longer to occur. That the mechanism involved in the skin-secreting response is vaso-motor is unlikely, in view of the fact that injections of histamine have no effect on the secreting reaction, while adrenaline produces a copious viscid secretion.—**I. Schrire and H. Zwarenstein**: Protein metabolism and the effect of injection of pituitary extracts on normal and castrated animals. Both anterior and posterior lobe extracts decrease the high creatinine excretion in castrated male rabbits almost to pre-castration levels. The effect on the normal rabbits is very slight.—**W. J. Copenhagen**: Sulphur as a factor in the corrosion of iron and steel structures in the sea. Observations on the film potential of twenty-one iron and steel structures gave a constant value of $-0 \cdot 3770$ volts (standard error $\pm 0 \cdot 0028$). The presence of a primary and a secondary film on sea-water corroded iron and the significance of sulphur in the primary film are discussed, together with the occurrence of sulphur in corroded zinc plates on ships' bottoms and the possibility that the constant film potential is an iron sulphide—carbon dioxide reaction.

ROME

Royal National Academy of the Lincei: Communications received during the vacation.—**G. A. Blanc**: Persistence of anisotropic structure in silica obtained by the action of acids on leucite. When a crystal of leucite is treated with a strong mineral acid until all the potash and alumina are removed, and is afterwards washed with water and allowed to dry in the air, it exhibits not only the original external crystalline form—which might indicate mere pseudomorphism—but also the internal crystalline structure characteristic of the complex $KAlSi_2O_6$.—**Vladimiro Bernstein**: Theorems relating to the singular points of Dirichlet's series.—**Maria Cibrario**: Preliminary studies on the linear equations to the partial derivatives of the second order of mixed hyperbolic-parabolic type.—**A. Del Chiaro**: The smoothing procedure of Schwarz.—**M. Haimovici and E. Popa**: Correspondence for parallel tangent planes.—**B. Hostinský**: Integration of linear functional transformations.—**L. Laboccetta**: The effective integration of discontinuous functions (1): Summation of punctiform functions.—**L. Allegretti**: The structure of the line 6708 of lithium observed in emission. In agreement with previous results, the distance between the two principal components of this line is found to be $0 \cdot 155$ A. and that between the satellite or less intense component and the component of greater wave-length, $0 \cdot 149$ A.—**L. Pincherle**: A perturbed series of the spectrum of ionised aluminium. Confirmation is obtained of the interpretation recently given by Shenstone and Russell of certain irregular series in line spectra which diverge somewhat from Ritz's form.—**I. Ranzi**: New arrangement for investigating the structure of the Heaviside region.—**G. A. Barbieri**:

Electrolytic preparation of certain complex salts of divalent silver. The preparation of various dipyridyl-argentic compounds from the persulphate is described.—**R. Bigazzi**: A structural constant relating to changes of state. If T is the absolute temperature at which any change of state of a compound occurs, P the molecular weight, and p the specific gravity at 15/4°, it is found empirically that the formula $TP/p^2 = \text{constant} = K$ or, since the molecular volume $V = P/p$, $TV/p = K$ is valid for compounds of similar chemical structure. This expression has an advantage over the parachor, in that it contains only magnitudes which are either known or readily determinable. By the introduction of a factor of complexity c, which represents the greatest width of the graphic formula for any compound, the expression $TP/p^2c = K'$, which gives an approximate constant for the change of state of all molecules of different structures, is obtained.—**F. Garelli and G. Racciu**: Triphenyl phosphate as a cryoscopic solvent. Cryoscopic measurements show that, at 50°, sulphur dissolved in triphenyl phosphate has a molecular magnitude corresponding with the formula S_{10}. In the same solvent, iodine exists as I_2, trimethylenetrinitrotetramine as the trimeride $(CH_2N.NO_2)_3$, and indigo as the simple molecule $C_{16}H_{10}O_2N_2$.—**V. Famiani and V. Zagami**: Comparison between the reconstructive food values of certain vegetables and grain. After fasting, pigeons gain in weight more rapidly on a diet based on *Ervum lens*, *Lathyrus sativus* or *Lathyrus cicera* than on one based on *Triticum vulgare*. Moreover, the recovery of a given percentage loss of weight requires appreciably less of the former than of the latter diet.—**C. Andreatta**: New investigations on bianchite: synthetic bianchite. Crystallisation of a solution containing zinc and ferrous sulphates and sulphuric acid yields an isomorphous mixture of composition approximating to that of natural bianchite, for which the formula $(Zn, Fe)SO_4, 6H_2O$, with the ratio $ZnO : FeO$ very nearly 2 : 1, is established.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 18, 567–608, Sept. 15, 1932).—**Alan W. C. Menzies**: The vapour pressure of liquid water that has recently been frozen. T. C. Barnes has reported that water containing large quantities of trihydrol (associated water molecules) promotes the growth of algæ. If recently frozen water contains more such associated molecules than recently condensed water, it might be expected to show a different vapour pressure. Experiments at 25° and 3° with a glass differential pressure apparatus showed no such difference.—**Henry B. Ward**: The origin of the landlocked habit in salmon. Such races of salmon are known from many rivers of North America and elsewhere, often where there is no barrier preventing the fish from migrating to the sea after hatching in the upper waters. They are generally smaller than the sea-run species from which they probably originated. It is suggested that the chief factor in the production of such dwarf races is temperature of the surface water, rather than a stream barricade or food abundance. For example, a power dam creates a lake with little current, the surface waters of which quickly attain a temperature too high for the young fish; the fish descend to the cooler layers and, finding no outlet, remain there. Glacier action and earth movements in the past may have had similar effects, leading to the appearance of landlocked fish in streams which now have no barriers.—**N. A. Wells**: The importance of the time element in the determination of the respiratory metabolism of fishes. Fish were transferred to a constant flow apparatus and their oxygen consumption measured. For the species used, *Fundulus parvipinnis*, of average weight 6 gm. at a temperature of 13° C., the average value over a period of eight hours after a lapse of twenty-four hours or more in the respiratory chamber represents the normal metabolism. High values are obtained while the fish are settling down in their new environment and any disturbance immediately increases the metabolic rate. The temperature of the environment before entering the respiratory apparatus has little effect on the general trend of the metabolism.—**Otto Struve**: Thermal Doppler effect and turbulence in stellar spectra of early class. The lines of these spectra have cores of the width required by the theory of Doppler broadening. The fuzzy lines in the spectra of A, B and O stars are probably due to 'rotational' broadening rather than to turbulence.—**O. Struve and W. W. Morgan**: On the intensities of stellar absorption lines. A brief report of work in progress at Yerkes Observatory. It is known that the relative intensities of the singlet and triplet lines of helium are not the same in all stars; there are similar differences in the doublets and quartets of singly ionised oxygen and even in the multiplets of other elements. No explanation is offered.—**H. S. Vandiver**: Note on the divisors of the numerators of Bernoulli's numbers.—**G. A. Miller**: Non-group operations.—**Arnold E. Ross**: On representation of integers by quadratic forms.

Technical Education and Progressive Industry*

As a result of a recent visit to France, Belgium, Czechoslovakia and Holland to investigate technical education at the apprenticeship stage and trade schools in particular, two Board of Education inspectors, Messrs. A. Abbott and J. E. Dalton, have produced a valuable report on the relation of technical education to industry in Great Britain. Their conclusions derive greater weight from the moderation of the report.

The report shows clearly that while Continental countries direct their main effort towards giving a severely practical training to recruits before they enter industry, their full-time pre-employment schools being in effect a part of the industrial rather than of the educational system, in Great Britain the whole system of technical education has been built up on the basis of the part-time instruction of young persons *after* they have entered industry. While, for example, we regard the technical school mainly as a place where instruction in the principles underlying industrial practice should be given and have usually left training in workshop methods to the mill or works itself, in France the technical school is looked upon as an institution which combines a good deal of instruction in workshop methods with instruction in the principles underlying this practice. The junior technical school, in fact, remains part of the educational system of Great Britain and is not part of the industrial system; and there is a definite difference in the way in which the burden of training recruits to industry is shared between the community and the employer in Great Britain and on the Continent.

The causes of this divergence are partly to be found no doubt in the greater interest taken in technical education in the countries visited than in Great Britain and particularly in the profound conviction that technical education is a most powerful instrument for maintaining and increasing industrial efficiency. The Belgian Ministry, for example, regards technical education as not merely an attempt to train well-disposed and ambitious individuals to occupy higher posts, but rather a definite effort at training an industrial army, officers and rank and file alike, which by its morale and technique will safeguard and strengthen the economic life of the State.

This view of technical education as organised

* Board of Education. Educational Pamphlets, No. 91 (Industry Series, No. 11): Trade Schools on the Continent. Pp. 110. (London: H.M. Stationery Office, 1932.) 2s. net.

to serve the needs of industry and the State is one to which the report rightly directs our attention and should assist in provoking that much needed public interest in the problems of technical education, from the lack of which it has suffered considerably. The individualistic view of education requires to be replaced by a wide vision of service for industry and the State if either public interest is to be roused or adequate co-operation secured between neighbouring local education authorities and between educational authorities and industry. Apart from the fact that certain of the weaknesses in our institutions for technical education are due to their having been built up too much in response to a demand from below and not enough in response to requirements from above, the only secure basis for developments of technical education in Great Britain is a keener and more widely diffused appreciation of the benefits to be derived from it.

The present report is essentially a further plea for the definite planning of technical education in relation to the needs of industry and society as a whole, rather than in response to individual requirements or ambitions. Technical education is so significant a factor in industrial efficiency that the public interest demands that our system of training craftsmen should be kept abreast of the times. Although up to recent years, when the emphasis was on the personal factor, industry and commerce were able to rely on evening classes for the bulk of our technical education, this form of instruction cannot remain permanently as the chief provision of technical instruction in a modern industrial State. It should be replaced to a considerable extent by a system which involves less strain on the student and yields fuller results. The tradition in Great Britain of evening education should, in the interests alike of the students, of industry, and of the community, play a much smaller part than at present in our educational system.

The justice of this argument is difficult to deny. So far as the cost of extending the volume of technical education for part-time day students is concerned, a considerable amount of accommodation in technical schools is at present vacant during the day and the increased cost would be mainly in payment of instructors. Apart from this, the present unemployment situation and the general problem of leisure with which we are confronted suggest that part-time day instruction is a rational method of completing any deficiencies in the education which the recruit to industry has previously received, and one thoroughly justified on economic grounds even in times of financial stringency.

While placing its main emphasis on the extension of part-time post-employment instruction and particularly its transfer from the evening to the day, the report also advocates a steady but discriminating increase in the number of junior technical schools to meet the needs of a particular type of pupil and of special industries or grades of occupation, as well as an increase in the number of junior vocational schools which are definitely trade schools. It is considered that it would be a mistake to replace the junior technical school as it exists in England by any form of pre-employment training seen on the Continent.

There is, however, a further fundamental problem which is also involved in any deliberate re-planning of technical education in relation to industry and commerce, and to this also the report directs attention. Even educational enthusiasts have often failed to realise that the development of the educational system is a social and economic phenomenon of profound significance, and accordingly the check to the vertical mobility of labour which is becoming apparent under the new conditions of industry and education has yet to receive full examination. Industry itself, for example, has not fully realised the bearing upon industrial recruitment and promotion, of the educational changes which now provide it with two separate streams of recruits differing considerably in quality according to their selection or not at the age of eleven years for admission to schools with a leaving age higher than fourteen years. The number of the selected group inevitably will, as a whole, outstrip those of the unselected group in competition for the more responsible and attractive posts in industry, and the responsible officers of industry will thus come from a group of individuals picked out at an early age for prolonged education.

The question of the educational provision to be made for the rank and file of industry demands increasingly the most serious consideration. Very few of them can hope for much promotion and only very exceptional boys of great ability and determination can look forward to securing posts higher than that of foremen. In addition, technical education, which until quite recently has been mainly post-elementary in character, has to adapt itself to meet more efficiently the needs of the

growing numbers of students who have received a prolonged general education. Both facts—the entrance to industry of considerable numbers of youths with a prolonged general education and the diminished incentive which ambition can provide—may, however, decrease the attendance of the next generation at vocational evening classes. It is probable that, as has been suggested by Lord Eustace Percy, the technical part of such education will best be arranged in part-time day classes while evening classes are reserved for more general instruction involving something in the nature of change and relaxation, and that evening study in particular should be organised on lines calculated to preserve or restore the adaptability of the British workman, the loss of which is under modern conditions as serious for the worker as it is to industry itself. It is only as we are bold enough to make our schools the creators of new social standards, instead of the slaves of existing ones, and to demand a development of those parts of our educational system which can admit men and women to the coveted social status which at present belongs to the professions and the middle and higher walks of commerce, that we can expect to disperse much of the prevailing dissatisfaction and unsettlement in our industrial society. The rigidity of both the skilled or semi-skilled worker, and their reluctance to undertake any other kind of occupation, are due alike to the scarcity of industrial standards entitling the worker to such respect and the fear of losing any scanty rating once acquired with a particular occupation.

Messrs. Abbott and Dalton, in the report before us, have produced a valuable document which enables the whole field of technical education to be surveyed in relation to modern industrial requirements. In addition to their emphasis on technical education as a factor in commercial and industrial efficiency and their discussion of the respective contributions of part-time instruction, the technical school and the senior elementary school, they direct attention to such important aspects of the problem as the training of teachers and the effect of vocational guidance. The whole situation calls for the closest and most careful study and co-operation by industry and by educational authorities. Industrial efficiency and the widest national interests will only be served by wide views and a deliberate policy conceived not in relation to immediate financial contingencies but in regard to the 'long range' requirements of our industrial society. In the present position, this can only be secured as the industrial and commercial professions consciously and actively contribute a liberalising influence to the standards of education like that exerted by the 'liberal' professions in previous centuries, and assist in a firm resistance to any reactionary or short-sighted policy which may jeopardise the future efficiency of industry or the welfare of society. Scientific workers engaged in industry no less than in teaching have a decisive part to play in the formulation of a practical policy of technical education and of a liberal and constructive philosophy capable of taking the wide views so essential if the educational system is to serve its primary purpose of fitting the coming generation to take its place in the life of a scientific age, in which vocational demands are ever increasing.

Max Planck's Theoretical Physics

(1) *Theory of Electricity and Magnetism.* Pp. xii + 247. 10*s.* 6*d.* net. (2) *Theory of Light.* Pp. vii + 216. 10*s.* 6*d.* net. (3) *Theory of Heat.* Pp. viii + 301. 12*s.* net. Being Vols. 3, 4 and 5 of *Introduction to Theoretical Physics.* By Prof. Max Planck. Translated by Prof. Henry L. Brose. (London: Macmillan and Co., Ltd., 1932.)

QUANTUM theory originated in the work of Prof. Max Planck of Berlin in the year 1900. It is significant that the new theory arose out of a discrepancy between theory and experiment in a somewhat recondite field of investigation, described by Lord Kelvin as one of the clouds over nineteenth century physics. The subject of research was the character of the heat radiated from a hot body—at first glance not a very promising field for anyone looking out for startling discoveries. But when we reflect that this 'radiation problem' involves the whole question of radiation and its relations to tangible matter, its importance becomes evident. Planck's paper "On the Distribution of Energy in the Normal Spectrum" was read before the German Physical Society on December 14, 1900. He had already announced his radiation formula, and in this paper he described a method of deducing it from the hypothesis that the rectilinear oscillator (dipole) of Hertz, regarded as a source of radiation, can possess energy only in integral multiples of the quantum $h\nu$. The universal constant, h, of

the radiation law, being the product of energy and time, was called the elementary quantum of action.

Planck himself has always adopted a cautious and conservative attitude towards the new theory, and time and again strove to bring about agreement with the principles of classical dynamics. "Since nothing probably is a greater drawback to the successful development of a new hypothesis than overstepping its boundaries, I have always stood for making as close a connection between the hypothesis of quanta and the classical dynamics as possible, and for not stepping outside of the boundaries of the latter until the experimental facts leave no other course open."

One of the pressing problems for the teacher of physics at the present time is to know how to deal with the ever increasing mass of new material without sacrificing what is essential of the old. For this reason it is a matter of moment that a brilliant and original theorist should have found time to place on record a statement of what he considers of fundamental importance to the student of physics, and we are grateful to Prof. Planck for his successful labours. His earlier works on thermodynamics and heat radiation had led us to expect a well-balanced and lucid account of modern theoretical physics, and in the three volumes now before us we are not disappointed. Volumes on general mechanics and the mechanics of deformable bodies form the first two of the series of five works comprised in Prof. Planck's "Introduction to Theoretical Physics". The translation into English is in the competent hands of Prof. Henry L. Brose.

(1) The volume on electricity and magnetism is essentially deductive in its method. Two fundamental ideas are employed in the development of the subject—the Principle of Conservation of Energy, which is given priority, and the Principle of Contiguous Action. This second principle, which postulates action by contact as opposed to action at a distance, is the basis of Maxwell's theory. "Everything which happens at a certain place at a certain time is completely and uniquely defined by the events which have occurred immediately preceding it in the immediate neighbourhood of the place." It is claimed that this theory owes its sovereign position over all others to its greater definiteness and simplicity. The book accordingly starts in somewhat unusual fashion by giving expressions for the energy of the electromagnetic field, followed by Poynting's vector for the flux of electromagnetic energy. This procedure is of special interest in view of the criticism which Poynting's theorem has received in recent years. From these principles Maxwell's fundamental equations for the electromagnetic field are derived. The electrostatic field and the magnetostatic field are then discussed, together with molecular and ponderomotive actions in the stationary field. Finally, quasi-stationary and dynamical processes are considered and also the limits of the electrodynamics of Maxwell and Hertz. This all too brief summary will serve merely to give some idea of the scope of the work, which deserves the careful attention of the advanced student. The treatment of the different systems of units and the dimensions of electric and magnetic quantities deserves special commendation.

(2) In the first three volumes of the series matter is assumed to have absolutely continuous properties, but in the volume on light the atomic point of view must be adopted. This is necessary in dealing with dispersion, for the interaction between light waves and vibrating particles must then be considered. Some of the more daring speculations in quantum theory were due to Einstein, who in 1905 put forward the hypothesis of 'light quanta', and later applied quantum ideas to account for the thermal capacity of a solid at low temperatures. In the present volume the opportunity is seized of showing how optical theory links up with quantum mechanics. The analogy between classical mechanics and geometrical optics is described, and it is shown how L. de Broglie based on this analogy an explanation of quantum phenomena. Schrödinger afterwards developed the idea further and embodied Hamiltonian and optical principles in his wave equation.

(3) The last volume deals with heat because the theory occupies a special position as compared with other physical theories. The First Law of Thermodynamics is merely a particular case of the Principle of the Conservation of Energy, but the Second Law introduces a new conception which is peculiar to heat. As soon as heat enters into the question, the sequence of events tends to approach a definite end in which a state of thermal equilibrium is established. "Hence all occurrences in which heat plays a part are in a certain sense unidirectional, in contrast with mechanical and electromagnetic events, which can equally well take place in the reverse direction, since for them the sign of the time factor is of no consequence." Perhaps some caution is advis-

able before dogmatising on this difficult question, in view of the limited nature of human experience. In the first two parts of the book the author deals with heat in bodies, and afterwards also with radiant heat. The third part is concerned with the classical laws of radiation and the last part contains a valuable account of Planck's own work on the theory of quanta as applied to the energy distribution in the normal spectrum, and the equation of state of material bodies.

These volumes should take their place in the library of every physicist. H. S. ALLEN.

Antarctica

The Conquest of the South Pole: Antarctic Exploration 1906–1931. By J. Gordon Hayes. Pp. 318 + 24 plates. (London: Thornton Butterworth, Ltd., 1932.) 18*s*. net.

DR. H. R. MILL'S "Siege of the South Pole" was published in 1905. It was a scholarly book, full of the author's enthusiasm for the explorers and their work, and with just sufficient of the popular to recommend it to the general as well as to the informed reader. Many regard it as the best book on the Antarctic, and it is certainly among the first half-dozen, occupying an honoured place with the travel narratives themselves; with Scott's "Voyage of the Discovery", Shackleton's "Heart of the Antarctic", and Shackleton's "South".

Dr. Mill's book ended with the period of the British Antarctic Expedition, led by Capt. Scott in the *Discovery* in 1901–4. Fresh expeditions from that date have followed one another in rapid succession, and in 1911, for example, there were as many as seven separate parties in the field belonging to five expeditions. As Dr. Mill says in his introduction to Mr. Hayes' book, he was soon bombarded by demands for a continuation; and he made up his mind to rewrite and modernise the "Siege". Other factors however intervened, and perhaps providentially. It is doubtful if a sequel or a revision can ever repeat a first success. Dr. Mill in the end had to give up the idea either of rewriting the "Siege" or publishing a fresh book to deal with the last twenty-five years. Concurrently, however, he had found Mr. Gordon Hayes more than willing to undertake the work and anxious also to be guided by his predecessor. The present book is the result, written by Hayes and approved by Mill.

The expeditions dealt with begin with Shackleton's journey to the plateau in 1909, when he outdistanced his predecessors by more than 400 statute miles. Hayes, like Mill, is carried away with enthusiasm. Charcot, Amundsen, Mawson and Scott take their place among his heroes; and if Amundsen, the conqueror of the South Pole, gets less space than the others, it is a tribute probably to the speed of his dash south and to the efficiency of his plans. In the author's opinion the heroic age ends with the adventures of the *Endurance*, when the ship was lost, but Shackleton brought his party back intact.

For the later expeditions, Mr. Hayes prefers the adjective mechanic rather than homeric, but not to the exclusion of heroism. Wilkins, Riiser-Larsen, and Byrd are all flying men, and they have all of them shown how discoveries are now dominated by the machine. There is a limit, however, to the effectiveness of the aeroplane, as exploration, in its widest sense as distinct from discovery, must still be done on the ground. This is driven home both by Hayes and by Mill; the aeroplane may be the eyes of the Antarctic leader; to explore and to conquer is still the work of the man on the ground. The motor sledge will be his ultimate standby; but meantime dogs and men may still make records in the Antarctic. J. M. WORDIE.

Structure of Crystals

The Structure of Crystals. By Ralph W. G. Wyckoff. (American Chemical Society Monograph Series, No. 19.) Second edition. Pp. 497. (New York: The Chemical Catalog Co., Inc., 1931.) 7·50 dollars.

DR. WYCKOFF'S monograph on "The Structure of Crystals" has, in the second edition, been revised so drastically that it is in effect a new book, since, although the experience gained from the first edition has not been lost and many of the figures have been retained, the original text has been sacrificed almost in its entirety. A most praiseworthy sequel is that the main text is actually shorter by 27 pages, but the bibliography, which began with 7 entries for 1912 and included 112 entries for the year 1922, has now expanded to 367 entries for 1930 and occupies altogether nearly eighty pages in the new edition.

The principal additions include an introductory chapter, which makes it easier to start reading the book, and new sections on the production of X-rays, the scattering power of atoms, atomic

sizes and co-ordination. The experimental chapters in Part I, "Methods of Crystal Analysis", have also been arranged in a different order. In Part II, "Results of Crystal Analysis", the old chapters dealing with oxides, chlorides, nitrates, etc., have also been displaced by chapters dealing with the types RX, RX_2, R_2X_3, RX_3, $R_x(MX_3)_y$, $R_x(MX_4)_y$, etc. These are preceded by a chapter on "Elements and Alloys", in which all the data available up to 1930 are summarised, and are followed by chapters on hydrates and ammoniates, silicates and organic compounds, all provided with similar tables and references to the bibliography.

The only fault which the reviewer has discovered is that in the new edition references are given exclusively to these tables, so that it is no longer possible from the index to trace the pages on which such familiar structures as those of rock salt and fluorspar are illustrated. On the other hand, the author has accomplished the unwonted exploit of writing a second edition of which the text is shorter and not less readable than that of the first, in spite of the enormous mass of additional knowledge with which he has had to deal. The new edition is therefore even more useful in 1932 than its predecessor was in 1924, and is likely to be in still larger demand.

Harvey's Successor

Early Science in Oxford. By R. T. Gunther. Vol. 9: *De Corde. By Richard Lower, London, 1669.* With Introduction and Translation by K. J. Franklin. Pp. xxxv + 374 + 8 plates. (Oxford: R. T. Gunther, 5 Folly Bridge, 1932.) 21*s*.

THOSE who follow the trend of human anatomy in England may have noted the appearance of certain additions which Dr. Franklin, of Oriel College, Oxford, has made to our knowledge of the venous system. It is uncommon in these days to find an anatomist or physiologist who, before setting down the contribution he is to make to modern knowledge, takes pains to discover not only what his immediate predecessors know but also what his remote predecessors have discovered, in the particular field of inquiry he has undertaken.

Dr. Franklin has the happy gift of compelling the past to help in unravelling the problems of the present. By rendering into English Richard Lower's "Tractatus de Corde" he has given its author a high and distinguished place amongst anatomists and at the same time has rendered a service to modern anatomy, for beyond doubt, the utility of Richard Lower's investigations is far from exhausted.

Harvey's discoveries were published in 1629; Lower was born in 1631; his tract on the heart was published in 1669, twelve years after Harvey's death. A close study of Dr. Franklin's translation leaves no doubt as to Lower's position; he was, after Harvey, the greatest anatomist produced in England during the seventeenth century. He came against medical men who still doubted the truth of the functional explanation which Harvey had given of the heart and of the blood vessels of the body. Following in Harvey's footsteps, he again submitted the heart to anatomical analysis and experimental proofs and discovered many truths, supplementary to those of Harvey, which have been rediscovered in quite modern times. Even to-day, physiologists have something to learn from him regarding the manner in which the heart is fixed, so that it can serve as a pump; his description of the intricate arrangement of the musculature of the heart and his conception of the manner in which the blood is expelled from the heart by its musculature—"like the wringing of a linen cloth to squeeze out water", come nearer the truth than are to be found in modern textbooks.

In all his investigations, Lower was guided by the assurance that the clue to function was structure, but he also knew that final proof had to be sought in experiment. In the course of his experiments he produced conclusive evidence that it was the absorption of air in the lungs which gave blood its arterial colour.

Lower, it must be admitted, made many mistakes in his attempts to explain the structure of the human body, and his name has come down to modern times attached to one of these. Dr. Franklin reproduces not only a facsimile of the original text of "De Corde" but also of its illustrations. Fig. 1 is a drawing of a heart—which is said to be human. The superior and inferior venæ cavæ are made to enter the right auricle at an angle and so close together that their adjacent margins form a projection or swelling. This projection was described by Lower and has been named the "tubercle of Lower". One may well suspect that the heart figured by Lower was not human, for it shows a prominent caval angle which is characteristic of the heart of quadrupeds and not, as he asserted, of the human heart.

Lower deserved a better fate than to have his name handed down to posterity linked to one of his mistakes. Fig. 1 of Plate V gives a view of the interior of the human left ventricle in which is rendered a most faithful representation of the conducting system of the heart, the true nature of which was discovered by Tawara only twenty-five years ago.

Lower was one of the brilliant band of scientific men who made their home in the University of Oxford during the Commonwealth and founded the Royal Society after the Restoration. Robert Hooke and he were members of Christ Church, and it is right that Dr. R. T. Gunther should have devoted the ninth volume of "Early Science in Oxford" to the work of Lower, since the eighth was given to that of Hooke.

Short Reviews

(1) *How to be Happy though Human.* By Dr. W. Béran Wolfe. Pp. xiv + 374. (London: George Routledge and Sons, Ltd., 1932.) 10*s.* 6*d.* net.

(2) *Discovering Ourselves: a View of the Human Mind and how it Works.* By Dr. Edward A. Strecker and Dr. Kenneth E. Appel. Pp. xiii + 306. (London: Chapman and Hall, Ltd., 1932.) 15*s.* net.

(3) *Effective Thinking.* By Joseph Jastrow. Pp. xiv + 263. (London: Noel Douglas, 1932.) 7*s.* 6*d.* net.

(4) *The Sex Education of Children: a Book for Parents.* By Mary Ware Dennett. Pp. viii + 142 + 4 plates. (London: George Routledge and Sons, Ltd., 1932.) 3*s.* 6*d.* net.

WE notice these four books together because they all bear upon a common theme—the art of living. They all exemplify the fact that medical men and psychologists are partly taking the place formerly occupied exclusively by moralists, in teaching that art. "Mental hygiene," says Dr. Wolfe, "is the science of the hour. In its twenty-five years of existence this infant among the sciences has already contributed a distinctive flavour to the twentieth century." To like effect Drs. Strecker and Appel write—"There seems to be a general need for a more intelligent understanding of mental hygiene." Both these books take the view that, the value of physical hygiene being now everywhere accepted, mental hygiene must have its turn. Dr. Wolfe owns Alfred Adler as his leader. But he stands firmly on his own feet, basing his treatment of the subject largely upon cases from his private and clinical practice. He has written an excellent book, which deserves lengthier notice than it can receive here. The same may be said of "Discovering Ourselves". The authors of this book help the general reader by the use of illustrative diagrams, quite effective in their way. They write sanely and sensibly, and so clearly that no educated reader can miss their meaning. One can say so much, without committing oneself to all their views.

In the third book on our list, we pass from mental to 'logical hygiene'. The author makes it clear that 'effective thinking' does not come entirely by the light of Nature. But instead of the logic of the textbooks, he gives an analysis, popular but not shallow, of the technique of thinking, and of the impediments in the way of accurate thought. He makes us wish that our politicians and journalists and other modern guides could be compelled to make a careful study of his book.

In the fourth book we pass to the much discussed subject of sexual hygiene, certainly a most important factor in the art of living. Limitations of space forbid us to say more than that it is one of the best books of its kind we have seen. It is sane, sound, and admirably written.

A Short History of Atomism: from Democritus to Bohr. By Joshua C. Gregory. Pp. vi + 258. (London: A. and C. Black, Ltd., 1931.) 10*s.* 6*d.* net.

IT is the epic of the successive dynasties of the atom that Mr. Gregory sets himself to recount in his very interesting book. From Democritus, who was the first to discuss atoms, down to the present day, we are given a panoramic but accurate description of the various types of atoms which have held the field of science and speculative philosophy; and though a bibliography would have been helpful, the absence of notes is more than compensated by the specialised knowledge that Mr. Gregory has of this very difficult subject.

It is, of course, the modern period which is considered at great length by the author. We are shown, for example, how Daltonian atomism, striking into thought about midway between the conceptions of Boscovich and Faraday, formed the background of the remarkable labours of Gay-Lussac, Avogadro, Faraday, Prout, Thomson, Rutherford, Helmholtz, Goldstein, Röntgen, Kelvin, Curie and others. But though this revival of the Democritean and Newtonian atom held its own until the end of the nineteenth century, it had finally to give way to the electrical structure of matter, a conception which was steadily invading science when Thomson accepted Kaufmann's hypothesis that the mass of β-particles was entirely electromagnetic. Democritus and Epicurus would have been surprised at the complicated types of atoms that have been constructed since; though they would feel more at home with the spontaneous swerves which, without any apparent cause, hurry the atoms into their disintegrating course. Heisenberg's principle of indeterminacy, coupled with the developments of wave and quantum mechanics, will no doubt lead

us into new conceptions about the atoms. Besides their scientific and perhaps practical interest, the question arises whether the new atomic theories, now in their period of gestation, will lead us away from instead of into reality. T. G.

Laboratory Manual of Organic Chemistry. By Dr. Harry L. Fisher. Third edition, revised. Pp. xvii + 368. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 13*s*. 6*d*. net.

ADDITIONS in the third edition of this manual include general notes, sixty-eight experiments and a large section devoted to methods of quantitative organic analysis. The style is clear and the subject matter has been brought up to date. The book differs from most of the other practical organic chemistry books in that, instead of describing a large number of preparations from which some can be selected for the student to perform, all the experiments described can be and are intended to be completed by the student during his course, and on completion he should have practical experience of all the processes described in the book.

The experiments, to each of which a series of questions is appended, appear to have been chosen to give the student a wide experience of the manipulation of the various types of apparatus used in organic preparation. The manufacture by young students of such materials as dry metallic acetylides and molecular sodium is, however, not without risk.

The chief merit of the book is the inclusion of a surprisingly large number of those little tips which make the difference between the technique of the student and the capable research worker and which are usually left to be learnt from personal experience and one's fellow workers. The book is well worth the attention of those responsible for laboratory courses. L. C. N.

Müller-Pouillets Lehrbuch der Physik. Elfte Auflage. Herausgegeben von A. Eucken, O. Lummer, E. Waetzmann. In 5 Bänden. Band 4: *Elektrizität und Magnetismus.* (1) Teil 1: *Grundlagen der Lehre von der Elektrizität und dem Magnetismus.* Bearbeitet von Siegfried Valentiner. Pp. xxi + 734. 47.50 gold marks. (2) Teil 2: *Technische Anwendungen der Elektrizitätslehre* (*Elektrische Maschinen, Kraftübertragung, Telegraphie*). Bearbeitet von H. Decker, E. Flegler und G. Möller. Herausgegeben von Siegfried Valentiner. Pp. xvi+462. 30 gold marks. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1932.)

"MÜLLER-POUILLET" needs no bush. The fourth volume of this standard treatise is divided into two parts, dealing with the fundamentals of the 'classical' part of electricity and magnetism, and with certain technical applications respectively. The treatment is full and thorough, while remaining elementary in character, and emphasis is laid on descriptions of measurement and instruments, rather than on developments of a formal mathematical type. The technical applications dealt with are those of most concern to the physicist, and are handled in thoroughly interesting and competent fashion. The volume is well illustrated and documented, and the teacher of physics will find it a most useful addition to his bookshelves. A. F.

Economic Geography of Europe. By Prof. W. O. Blanchard and Prof. S. S. Visher. Pp. ix + 507. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 17*s*. 6*d*. net.

THERE was need of a textbook on the economic geography of Europe that discussed broad issues and was not overburdened with facts and figures. This volume largely fills the gap. It was prepared for American students but that is no disadvantage since it appears to be singularly free from bias and treats the whole of Europe impartially.

The first part of the book treats Europe as a whole, starting from the essentials of physical geography. The second and longer part takes the different countries in turn, and this part is perhaps the most valuable, though apt to be superficial in places. It is written in a readable style and care has been taken not to clog the pages with facts of location or figures of trade, though these are not neglected where necessary.

There are many excellent maps and diagrams and careful bibliographies to each chapter. In an end pocket is a large folded 'physiographic diagram' of Europe which is in the nature of a pictorial map of surface features. This should prove useful even in the absence of a key to the regions.

The Open World: Three Lectures on the Metaphysical Implications of Science. (The Terry Lectures.) By Prof. Dr. Hermann Weyl. Pp. vi + 84. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1932.) 9*s*. net.

THIS book, which makes delightful reading, expresses the conviction that modern mathematics and physics make the world appear more and more as an open one; that is, they point to a world beyond the actual structures by which science describes the bounds of our positive knowledge. Science can do no more, however, than show us this open horizon; we must not by including the transcendental sphere, attempt to establish anew a closed though more comprehensive world. This main thesis is developed in three lectures on God and the universe, causality, and infinity. The profound and provoking opinions put forward by Prof. Weyl are a valuable addition to the testimonies expressed by prominent scientific workers as to the real value of their professional experiments and studies. T. G.

Tropical Plant Diseases: Their Importance and Control*

By Dr. E. J. BUTLER, C.M.G., C.I.E., F.R.S.

IN the great tropical and subtropical plantation industries, such as tea, rubber, coffee, cocoa, citrus fruits, etc., large areas of permanent crops are cultivated on capitalistic lines with uniform and usually white control. On an estate of hundreds or even thousands of acres, often under highly intelligent supervision and where the produce may be worth a great deal of money, it is comparatively easy to get adopted improvements which are the results of scientific research, whether in the control of disease or in any other direction. It is quite a different matter, however, when one comes to deal with the crops grown by the indigenous people of the tropics for their own use. Their agricultural practices are rigidly traditional, their standard of intelligence may be low, money is scarce or even absent, and their crops are raised in small holdings, often subdivided to an almost incredible degree. I once had occasion to acquire 17 acres for expansion of an agricultural research station in India and found 30 families and 91 individual plots represented in this piece of arable land. In such conditions—and they are those under which a great part of the population of the world lives—"the cultivator's ways and the sheep's ways tend to be much the same", as an Indian proverb says, and however well the traditional agricultural methods are followed, the cultivator is apt to be helpless in an emergency as, for example, an outbreak of epidemic plant disease.

It is not surprising that the earlier plant pathologists who worked in the tropics, from the time when Marshall Ward went to Ceylon in 1880 to fight coffee leaf disease when it was already too late to save the industry from ruin, should have concerned themselves mainly with the diseases of the great export crops. A study of the reports of fifteen or twenty years ago will show that for practical purposes, India was the only tropical British possession in which it was the policy of the agricultural departments to devote much of their attention to the crops grown by the people of the country for their own use. During the past ten years, however, there has been a considerable improvement in this respect in the British Colonies, especially those of tropical Africa. Most of the colonies have one, and a few have two, plant pathologists attached to the agricultural departments and where as in several of them there are no plantation crops, the needs of the village cultivators are receiving attention. Even in some of the more advanced 'plantation' colonies such as Ceylon and Malaya, the large plantation industries have now organised their own research departments, leaving the Government departments of agriculture free to concentrate on the improvement of the local crops and methods of farming.

Such improvements are likely to increase the responsibilities of the plant pathologists. New and improved varieties of crop plants are liable to become attacked by diseases from which the old ones had become immune through age-long selection, and more intensive methods of farming often have a similar result. The great activity in crop improvement that has been characteristic of agricultural development in the United States and Canada since the beginning of the present century, has been accompanied by such an increased call on the services of plant pathologists that each of the staple crops has, not one but many, men engaged in the study of the cause and control of the diseases to which it is liable. As similar efforts are made to improve the staple food crops of the tropics similar needs will be felt. There are clear indications from the work on rice in Japan that even in a crop such as this, which in India is one of the healthiest of all the field crops, there is a number of diseases capable of becoming formidable obstacles to the introduction of improved varieties.

The two tropical cereals next in importance as food crops, sorghum and the bulrush millet, are much more subject to disease than rice, but very little work has been done on them in the tropics and even the full life-history of several of the common bulrush millet parasites is unknown. Still less is known of the diseases of the tropical pulses and other plants of economic importance, except those that are grown for export. Tropical plant pathology has not much to boast of in the study and control of village and field crop diseases; the number of man-years of work put into this branch of agricultural science is too small to have yielded much result and the difficulty of getting the native cultivator to change his ways, as well as his lack of means and general backwardness, has helped to induce a pessimistic outlook amongst those who are charged with the control of agricultural research and amongst the research workers themselves. Nevertheless, not only because there is great preventable loss of crops from disease in the tropics but also because a solid knowledge of the pathology of each crop plant is a necessary concomitant of all attempts at crop improvement, means must be found to surmount these difficulties. Little by little, openings for successful attack on them will appear, and however slow progress may be at first, the next fifty years are bound to see a great improvement in the crops and in the general agriculture of even the most primitive of the African Colonies. In this advance plant pathologists will have to bear an ever increasing share.

The work which has been done in India during

* From a semi-popular lecture delivered before Section K (Botany) of the British Association at York on Sept. 2.

the past twenty-five years or so illustrates some of the problems that the tropical pathologist has to face in dealing with village and field crops. When the Indian agricultural department was formed thirty years ago, extremely little was known of the diseases of tropical plants, though there were a few exceptions, such as sugar cane. The first work done in the mycological branch, therefore, was to make a survey of the diseases of the more important crops, and when many of these were found to be undescribed, a more intensive study of a few was undertaken and lasted a number of years. Two of them, one on palmyra and coconut palms and the other on rice, broke out in epidemic form and had to be dealt with on emergency lines, invoking the aid of the administrative services and leading, in the palm disease campaign, to legislation of the kind that is familiar in more advanced countries, where it becomes an actionable offence to own a diseased plant without reporting or dealing with it as prescribed. In the campaign against this disease, which was exterminating the palmyra in an area where this was the dominant tree and by far the most useful,* nearly a million diseased palms were cut out to save the rest. This and the subsequent legislative action and the discovery that many trees could be saved by removing the bud sheaths in the early stages of attack have been successful in preventing the spread of the disease and in keeping it within manageable proportions. The campaign cost the Government about £20,000; but the value of the palms cured by treatment was estimated at about £28,000 in 1921, and the number saved from infection must run into millions.

In other cases it soon became evident that the variety of the crop grown was exceptionally liable to disease either because of inherent susceptibility or because disease had been allowed to accumulate in the stock and was being transmitted when diseased material was used for planting each successive crop. In such cases the agriculturists of the department, each of whom had a district under his charge, became invaluable collaborators, both in observing the injury done to particular varieties and in introducing new or more healthy ones.

Then there were the cases where one had to make a direct attack on the parasite and try to kill it or to prevent its spores germinating by the use of fungicides. This at once brought one face to face with the economic limitations of village agriculture in countries like India, where the cultivator usually has little actual money at his disposal and can only borrow at exorbitant rates of interest.

Copper and sulphur have remained to the present day the chief weapons in the hands of the plant pathologists in their direct attack on fungal parasites. In India they have been used chiefly on the more valuable orchard and garden crops or as seed disinfectants on field crops.

* An ancient Sanskrit poem professes to enumerate eight hundred and one separate uses for the palmyra palm.

The relative infrequence of destructive epidemics of disease amongst indigenous crops in the tropics as compared with the great plantation crops is not due, I think, as is sometimes assumed, to the circumstance that the latter generally occupy larger continuous areas under the one crop, so that disease germs can multiply and infect more readily. In India there are large areas of village lands mainly under a single crop, as rice in 70 per cent of the cultivated land in parts of Bengal or cotton in 60 per cent of Khandesh. Freedom from disease in these cases is probably mainly due to disease resistance having become, through long experience, the determining factor in the selection of the varieties grown, the quality of which is liable to be a secondary consideration and is often decidedly low. In the plantation industries, on the other hand, quality which will enable the produce to compete in the markets of the world is so important that hardiness may be sacrificed. Examples of destructive epidemics in these crops are numerous and are not, as in the other category, usually due to newly introduced parasites. They are just as often due to an old parasite finding in a new variety a congenial host. They are sometimes also due to the considerable financial return leading to expansion of a plantation system into areas not naturally affording optimum conditions for the growth of the plant, so that its environment may become more favourable to the parasite than the host.

The recent wave of epidemic disease that has ravaged the cotton plantations of the Sudan may perhaps find a partial explanation in these considerations. When the great Gezira irrigation scheme, due in its inception to the genius of Garstin and Kitchener, was opened in 1925, it was already established that the highest quality Egyptian long-stapled cotton could be successfully grown in this previously arid waste. At the present time, approximately 200,000 acres of irrigated Sakel cotton is grown as the major crop in the gigantic plantation of 600,000 acres under uniform control and cropping, surely the largest arable farm in existence. During the first five years after the dam was built across the Blue Nile, cotton worth more than £12,000,000 was produced from the Gezira, and 150,000 people had settled where before there was only a scattered famine-stricken population.

The cotton disease known as blackarm occurs in all the cotton-growing parts of Africa, but it seldom causes much injury to the varieties grown by the people of the tropical regions, and the long-stapled kinds grown in Egypt escape damage apparently because the climate of Egypt does not suit the parasite. In the Egyptian varieties grown in the Sudan it became a formidable pest, being one of the main factors in reducing the yield per acre from 479 lb. in 1925–26 to 129 lb. in 1930–31. This represents a loss of more than 60,000,000 lb. of cotton on the area grown in the latter year, worth even at the low prices then prevailing, more than £800,000. As the disease is carried mainly

on the seed, an elaborate scheme of seed disinfection with the dust known as 'Abavit B' was carried through before the last season's crop was sown, the whole of the seed for this great area, representing more than 30,000 bags, being treated by specially devised seed dusters. Various other steps were also taken to combat the disease, and the yield, when harvest was completed last spring, was found to have risen again to a little more than 400 lb. per acre, or not far short of that of the earlier years.

In this case there is far more at stake than the saving of an industry, however important. The whole future of a province is in the balance. I cannot refrain from quoting a foreign observer who visited the Sudan two or three years ago. "The Sudan is the latest thing in European exploitation and it is the best." There has been "created a corps of agriculturists and entomologists to destroy the pests that attack the native crops; a group of veterinarians to look after and improve the native cattle; and a quite unrivalled body of biologists, bacteriologists, laboratory workers and doctors to fight native diseases. Trekking through the land are the government biologists and entomologists, experimenting, destroying pests, noting processes, giving advice. You rarely find them in the same place for two weeks running; these hardy scientists do even more work in the open than in their laboratories."

The West Indies present a very different picture from the Sudan. There, in some of the oldest of the British Colonies, generations of planters and settlers have been engaged in the tropical and subtropical cultivations of lands favoured by Nature to an unusual degree. Jamaica is the largest banana exporter of the British Colonies, having sent out 24,000,000 bunches in 1930, representing more than 50 per cent of the total value of her exports. In 1912 the first cases of the now notorious Panama disease of bananas in the island were examined by S. F. Ashby. Rigid quarantine measures were promptly introduced by the Director of Agriculture, Mr. H. H. Cousins, impressed by the ruin from this disease which had befallen the banana-growing enterprise in the Dutch Colony of Surinam between 1906 and 1910. As soon as a diseased plant was discovered, it and all the surrounding ones on an area of four chains had to be destroyed and the area fenced in. As a result, spread was slow, the number of cases annually not surpassing 1000 until 1921. Increase since has been at the rate of about 50 per cent a year, until by 1929, there were about 85,000 cases, involving nearly 140,000 plants. In the parish of Portland, the most diseased, some 9000 acres, or approximately one-tenth of the total estimated banana acreage of the island, have now been abandoned, for it has been found that commercial banana growing is impossible on land once infected, and the great United Fruit Company has already abandoned nearly 100,000 acres from this cause in Central America. The expenditure by the Government of some £60,000 in Portland no doubt prolonged the life of the plantations by ten years or more, but in the end has proved unavailing.

As there is no direct method of fighting this disease, which is due to a soil fungus, attempts to procure resistant varieties are being energetically carried out both in Jamaica and at the Imperial College of Tropical Agriculture in Trinidad. Varietal tests have shown that the Cavendish species of banana and some others are either highly resistant or totally immune. Botanists both from Kew and the West Indies have toured the world in search of varieties for trial and hybridisation and these are grown under quarantine and inspection at Kew before being sent on to Trinidad. Very large numbers of crosses have been made in Trinidad and Jamaica and some of the immune seedlings produced in the latter island have given bunches which were acceptable to the trade during the past year. The Trinidad seedling I.C.1 (Imperial College No. 1), a cross between the commercial Gros Michel and a wild species, has also shown remarkable immunity during six years tests, but the fruit still requires improvement.

It is estimated that within the next five to seven years, at the present rate of increase of the disease and the amount of suitable banana land left, the Jamaican export will begin to decline, and the decline is likely to be rapid unless a satisfactory resistant variety can replace the Gros Michel. The breeding work is difficult and slow. It is not easy for the stricken farmers to be patient. The whole population in the coastal parts of the parish of Portland has been brought up to the cultivation of the banana before anything else, and though an alternative crop of marketable value is desperately needed, it will take a long time to break down prejudices in a one-crop population. Many of the people have migrated, but many have remained to make a living as best they can. It is cold comfort to tell them, as there have not been wanting even scientific men to say, that these coastal lands, extraordinarily fertile though they be, are unsuited to the banana because the damp soil favours attack by Panama disease. The local Department of Agriculture has never taken that view but has striven hard to fight the disease, and the extra lease of life that it has given the industry, though insufficient in Portland, may yet save the banana cultivation of the island as a whole.

In the examples selected to illustrate the importance and control of the diseases of tropical plants, there is every gradation in severity from the sorghum smut which levies a moderate toll of about ten per cent of the crop on some millions of acres in India, to the Panama disease which completely exterminates the susceptible bananas and precludes replanting within any reasonable time. The success of the measures which have been adopted to control these diseases also shows every gradation from the complete control which is easy to obtain by disinfection against sorghum smut or by growing Cavendish bananas in Panama-diseased land, to mere alleviation which appears to be all one can hope for, but is yet sufficient,

against rubber mildew or the root diseases of limes. A consideration of these measures—ruthless eradication, the complete replacement of susceptible varieties, hybridisation or selection to obtain resistant plants, budding or grafting on resistant stocks, modifications in agricultural practices like stubble burning or pre-watering, and, finally, the direct attack on the parasite by steeping, spraying or dusting—indicates how varied is the task of the plant pathologist and how wide must be the foundations of his knowledge if he is to perform it successfully. The old conception of the mycologist, student of the fungi that cause disease, as adequately equipped to fulfil the duties of a plant pathologist, dies hard but it is dying. Like bacteriology in the realm of medicine, pure mycology is a necessary foundation and the mycologist a necessary collaborator, but he is not equipped either as a general practitioner or a specialist in particular diseases.

The practical man is often slow to admit that a destructive disease in a plant is due to agencies outside his control. Confronted with such he is inclined to seek for explanations other than the true one. He looks first for some disorder brought about by cultivation or inbreeding, or meteorological phenomena. Or he thinks that the soil is unsuitable or has become exhausted, or that the plant, if an exotic, has failed to become acclimatised. It is often not until all these have been tested and found wanting, that the true cause is fully realised. Experience has shown that it is unfortunately rare to find the explanation of serious disease in these directions and the dominating factor is usually the presence of a parasite, however much its activities may be favoured by secondary causes.

Failure to recognise the very varied weapons used by modern plant pathology and undue weight given to the secondary factors in the causation of disease have led, no doubt, to the suggestion which I have heard that the 'mycologist', as he is still called in most of the British Colonies, may be in danger of losing his position as one of the most essential members of any team of tropical research agriculturists. In actual fact there can be no question that, looked on as a member of a team and relying on the collaboration that must exist between him and the plant breeders and agriculturists, the plant pathologist is more needed now than ever. Improvement in the crops of the people and the quest of quality or the satisfaction of market fancies in the plantation crops can be relied on to be followed by increase in disease. Unless plant pathologists well versed in the pathology of the crop concerned are available—and they cannot be produced at a moment's notice—the examples I have given will be paralleled in every Colony in the British Empire.

The Cambridge Philosophical Society

THE Cambridge Philosophical Society was incorporated in 1832, by Royal Charter, through the grace and favour of William IV, and the centenary of that event has been celebrated recently. (See NATURE of November 19, p. 769.)

The history of this scientific organisation, which has maintained a high standard in past years, and remains unfailingly hopeful of the future, should be of interest, not only to historians of science, but also to laymen. The Cambridge Philosophical Society is of older origin than its royal grant by some twelve or thirteen years. In October 1819, as the outcome of conversations amongst a few interested persons, a notice was issued, signed by thirty-three members of colleges, inviting assistance in promoting a society "as a point of concourse for scientific communications". Success having followed this venture, the designated name was approved, rules were made, and a council elected for the year ensuing. The Chancellor of the University, H.R.H. the Duke of Gloucester, accepted the office of patron; that of president being assigned to the Rev. William Farish, Jacksonian professor of natural and experimental philosophy. In all the foregoing movements, Prof. A. Sedgwick, J. S. Henslow (afterwards Prof.), and Dr. E. D. Clarke (professor of mineralogy, 1808–22), were prominent. At an inaugural gathering, the last-named gave an address on the new project (separately distributed*). Reference was broadly made to the philosophical contributions of members of the University as being hitherto "frittered and squandered away" in detached and distant parts, almost to be without existence.

The first half of the nineteenth century witnessed the establishment of many scientific societies. The apprehensions of Sir Joseph Banks for the welfare, even the continuity of the parent tree, the Royal Society, were seen to have been needless, and indeed, at his death, in 1820 (whilst in office), however chequered in progress certain of the newcomers were, the writing was already on the wall in regard to alarmist notions. Among the new bodies were: the Horticultural (1804), Geological, London (1807), Geological, Penzance (1814), Institution of Civil Engineers (1818), Astronomical (1820), Zoological (1826), Geographical (1830), Entomological (1833), Chemical (1841). Cognate organisations were formed at Manchester, Glasgow, Hull, and other centres. Neither in the perplexing era of the seventeenth century, nor in the industrial nineteenth, were scientific societies born secure in the knowledge of powerful support. In all the instances above, initiation was *ex collegium*. In the case of the Cambridge Society, there certainly was an ample measure of University support and

*The Patent Office Library, London, possesses a copy (bound) on the title page of which is the pencilled signature, "J. Henslow, 1821," and there are textual annotations in the same hand.

favour, coupled, by the way, with financial help from the syndics of the University Press.

A few words are due to the Rev. W. Farish, first president of the Cambridge Philosophical Society. Born in 1759, he was educated at Carlisle Grammar School. He graduated in 1778, being senior wrangler and first Smith's prizeman. Farish was instituted Jacksonian professor of natural and experimental philosophy in 1813, succeeding the Rev. F. J. Hyde Wollaston, a brother of William Hyde Wollaston. Earlier (1794) Farish had been chosen professor of chemistry. In 1796 he published a plan of a course of lectures on arts and manufactures in relation to chemistry, a scheme in all likelihood derived in the main from his predecessor, who himself was responsible for "A Plan of a Course of Chemical Lectures". Farish was the author of six papers read before the Society, one of them (1820) under the title "On the Mode of Conducting Polar Navigation".

Space would forbid other than cursory notice of memoirs read in the first half-century of the Society's career. The chief publication began in 1820, entitled *Transactions*, supplemented in 1843 by *Proceedings*. They both enjoy a world-wide circulation now. In the spring of 1820, J. F. W. Herschel communicated three papers, and in 1835 came letters from the Cape of Good Hope detailing meteorological observations made there by him. Similarly, at the same meeting, letters were read from Charles Darwin containing accounts of the geology of certain parts of the Andes and South America. Very much later (in 1860), Darwin is writing thus to Lyell: "I had a letter from Henslow this morning, who says that Sedgwick was . . . to open a battery on me at the Cambridge Philosophical Society. Anyhow, I am much honoured by being attacked there, and at the Royal Society of Edinburgh". Faraday had written in 1823 accepting honorary membership. Airy, whilst yet a student at Trinity College, communicated a paper, followed by others, down to 1840. Whewell provided many papers. But such records are readily capable of indefinite extension, reaching into another half-century, and that is not practicable. Suffice that the names of some of the best-known exponents of science in almost all departments appear in the lists of past presidents. We learn that to-day, tea before meetings, as in "another place", fortifies those numerous authors whose memoirs have, of necessity, to be "taken as read". The separate publication of *Biological Reviews and Biological Proceedings* is an undertaking of recent years which has proved of great value.

It is of interest to record that at the annual general meeting in 1895, Prof. J. J. Thomson, president, in the chair, the subjoined resolution was adopted: "That the Fellows of the Cambridge Philosophical Society at this their first meeting since the death of Professor Thomas Henry Huxley desire to express their sympathy with Mrs. Huxley, and to record their sense of the depth of his influence on modern thought, and on the progress of biological science".

In its youthful period, aided by the lively interest of Prof. Henslow, the Society took pains to form collections exemplifying natural history. In process of time this important nucleus of a great museum was given accommodation elsewhere (1865). There has been gradually brought together a reference library of most creditable size, and it includes numerous runs or sets of scientific periodicals. The adequate and safe housing of this library—none too well assured at present—is receiving attention.

The Cambridge Philosophical Society, unlike many other scientific institutions, has no trust funds of its own, and has never had the good fortune to receive a legacy or other special benefaction.

T. E. JAMES.

Obituary

SIR DUGALD CLERK, K.B.E., F.R.S.

BY the death of Sir Dugald Clerk on November 12, following comparatively closely on that of Sir Charles Parsons, Great Britain has lost the two greatest engineers in history, at least in the field of power production.

To the imagination, to the detailed scientific research and still more to the lucid and admirable teaching of these two men, are due the whole modern system of power production as we see it to-day, on land, on the water, and in the air. Just as Sir Charles Parsons by his development of the turbine revolutionised and revived the use of steam until none but his methods are employed to-day, so Sir Dugald Clerk nursed the internal combustion engine almost from the day of its birth as a sickly infant of little more than medical interest, nursed and reared it, until to-day it has become the greatest factor in modern engineering—indeed one might almost say in modern civilisation. In the early stages of its infancy, when 'doctors' differed and none knew how to feed or tend it, it was Clerk who first explained to the faculty how its delicate interior functioned, how its growth and strength could best be fostered, and where its frailties lay. Since that day, Clerk watched ceaselessly over and reared this child and its offspring through many generations, until to-day it has peopled the earth, the sea, and the sky. Many thousands of 'doctors' in all the countries of the world have since adopted and specialised in the care of this fertile breed, but one and all, consciously or unconsciously, have drawn their inspiration and their methods from the teachings of Sir Dugald Clerk.

We are prone to set great store by invention, and Clerk's inventions in this field were many and important, the best known perhaps being that

of the two-stroke cycle engine; but inventors are plentiful and inventions mark phases only. The great value of Clerk's work lies rather in his brilliant analyses of the working processes, in his lucid presentations of these in a form which appeal alike to the student, to the purely scientific investigator, and to the practical engineer—these will live for ever.

In his earlier work Clerk could rely for his observations only on the very imperfect and erratic instruments which were available, but he sifted and supplemented these often conflicting observations with such judgment and insight, and with such a breadth of imagination, that all his deductions have stood the test of time and hold good to-day.

The value of Clerk's scientific work was enhanced greatly by the extraordinary charm of his personality, by his kindliness and encouragement and by the almost limitless trouble he took to assist and encourage all the younger generation. My first meeting with Sir Dugald Clerk was some twenty-five years ago. As a very young man I had invented, or thought I had invented, an improved type of engine; I had submitted this invention to a manufacturing firm, who had referred it to Sir Dugald Clerk. Sir Dugald sent for me and explained that, reluctantly, he had turned down my invention; he explained exactly why and urged me not to be discouraged—he suggested many ways in which the idea could be improved, and invited me to call on him at any time for any help or advice he could give. At once I fell a victim to his charm and the obvious sincerity of his kindness—a kindness which he bestowed on me from that time until the day of his death.

Too often one has to record the great work of a man left unrecognised and unappreciated until after his death. Fortunately this does not apply in Sir Dugald Clerk's case: his work was known and recognised all the world over and he was honoured, as was his due, by the leading scientific institutions of his day and by his innumerable friends and admirers. His scientific lectures were always a joy to attend, not alone for the value of the material they contained, but also for the sheer joy of listening to his beautiful diction and his pleasant voice.

H. R. RICARDO.

MR. T. G. SLOANE

THOMAS GIBSON SLOANE, of Moorilla Station, Young, New South Wales, who died on October 20, combined the unusual association of sheep-breeder, philosopher, naturalist in general and entomologist in particular. One of five sons of Alexander Sloane, of Mulwala, Murray River, a well-known merino expert, he was educated partly at the Scot's College, Melbourne, partly by tutor at home. There was a strong literary taste in the family, and a fine knowledge of the English poets was a background of his well-stored mind. He was sent to Sydney to learn business methods and returned to manage Moorilla for the firm of Alexander Sloane and Sons, which he inherited as his life-long home. Here he won numerous prizes for sheep at various shows; had a stud of his own registered in the flock book; kept accurate records of wool weights and was a regular attendant at Sydney sheep sales.

In Sydney, however, Sloane also met Sir W. Macleay and his scientific henchman, the late J. J. Fletcher, who became his lifelong friend; and in 1888 contributed his first paper on Carabidæ to the Linnean Society of New South Wales. Natural history was his passion, and I have never met any man who so closely and enthusiastically studied Darwin, especially "The Origin of Species".

As an entomologist Sloane was soon recognised as the Australian authority on the Carabidæ, though he later included the Cicendelidæ in his studies. But his mental horizon was too wide to allow himself to be limited to collecting and describing new species. Phylogeny and distribution greatly occupied him. His paper on the "Faunal Subregions of Australia" has often been quoted by later authors, while his "Classification of the Family *Carabidæ*" (*Trans. Ent. Soc. London*, 1923) has received wide notice. Sloane's "Table of Tribes" has been adopted as being the most satisfactory classification in existence.

Sloane contributed some sixty-one papers to various societies—the great majority to the Linnean Society of New South Wales—and described 595 new species, of which 557 were Carabidæ, including a few from New Guinea. With a world-wide correspondence, he found time to help his brother entomologists generously by naming their collections, until later years brought those economic worries that have especially troubled Australian pastoralists.

I accompanied him on many a distant trip through Queensland, Western Australia, New South Wales and Victoria. He was a delightful companion and a lovable friend, with an unlimited stock of yarns, and a good 'mixer' with bush folk, whom he understood. A retentive, but not a wide, reader, he avoided modern fiction, but collected a good library especially on Australian exploration and traveller naturalists. Generous in excess to others, sparing in his own needs, a stoic by nature and will, his last years were spent in hard work on his homestead. He passed away at the Burrangong Hospital, Young, a victim to cardiac asthma, leaving a widow, two sons and four daughters to mourn his loss.

H. J. CARTER.

MR. G. B. SCOTT, C.I.E.

BY the death of Mr. G. B. Scott, which took place at Bournemouth on November 20 at the age of eighty-eight years, a distinguished Indian frontier surveyor passed away.

Scott's memory carried him as far back as the stirring times of the Second Sikh War. He was educated at the Lawrence Military Asylum at

Kasauli, through which place, as a boy of thirteen years of age, he saw the British regiments march on their way from Simla to take part in the siege of Delhi.

Scott joined the Survey of India in 1863, and then began an adventurous career on the North-West Frontier. His camp was attacked by the tribesmen on several occasions and he had more than once to repel, with his small guard, determined onslaughts of much larger numbers. On one occasion in particular, he repulsed an attack of several hundred Allahiwals while he was on survey duty, having with him a guard of only twenty sepoys. For the gallantry he displayed on this occasion he was rewarded by Government with an honorarium and a sword of honour.

Some years later Scott repulsed a determined attack on his survey party by the Mohmands while at work in the Khyber Pass. He had to fight his way back to Fort Michni, losing three killed and four wounded, one of which he carried out of fire. He took part in the Black Mountain, Jowaki-Afridi and the Zob Valley expeditions, as well as the Second Afghan War.

Scott did some valuable work in map compiling at army headquarters at Simla, which earned him, in 1885, the commendation of the Commander-in-Chief (General Roberts). After five years surveying in Upper Burma he was appointed in 1894 to be superintendent of Land Record Surveys in the United Provinces, a post which he retained until his retirement in 1901.

This, however, did not end Scott's career, for he was employed to superintend the Cadastral Surveys in the Bundelkhand States of Central India. From 1910, for nearly three years he was surveying for the Anglo-Persian Oil Company, in West Persia, and in 1912–13 was engaged on the survey of tin mines in the Karenni country of south-east Burma.

Scott was the author of a Pushto vocabulary, "Twenty Years on the North-West Frontier", "Afghan and Pathan" and "Religion and Short History of the Sikhs". He was the holder of two medals and four clasps, and in 1914 the Companionship of the Indian Empire was conferred on him. He was much liked by everyone who had the privilege of knowing him.

H. L. C.

WE regret to announce the following deaths:

Viscount Dillon, C.H., who was president of the Society of Antiquaries from 1897 until 1904, on December 18, aged eighty-eight years.

Prof. John Glaister, emeritus professor of forensic medicine in the University of Glasgow, whose best-known textbook was "Medical Jurisprudence, Toxicology and Public Health", on December 18, aged seventy-six years.

Dr. W. J. Holland, emeritus director of the Carnegie Museum, Pittsburgh, known for his work in museum administration and entomology, on December 13, aged eighty-four years.

Mr. H. A. Roberts, for more than thirty years secretary of the Appointments Board of the University of Cambridge, on December 18, aged sixty-eight years.

News and Views

Bicentenary of Sir Richard Arkwright, 1732-1792

ON December 14 at the Science Museum a public lecture was given by Mr. F. Nasmith, under the auspices of the Newcomen Society, to commemorate the bicentenary of the birth of Sir Richard Arkwright, the inventor of the spinning machine known as the water frame and the founder of the factory system of cotton manufacture as we know it to-day. In introducing Mr. Nasmith, Mr. H. W. Dickinson, president of the Society, said that it is one of the aims of the Society to direct attention to the great inventors and engineers who are among the world's chief benefactors, and it is of interest to recall the remark of Lecky the historian, who said that it was largely the cotton mill and the steam engine which enabled Great Britain to stand the strain of the Napoleonic wars, and that Arkwright and Watt deserved statues as much as Wellington and Nelson.

To understand fully the remarkable influence of Arkwright's work on the development of the factory system in the cotton industry, Mr. Nasmith said it is necessary to realise the conditions which prevailed when he commenced to take an interest in spinning. Textile manufacture when he was born was a purely domestic industry, carried on by manual labour and with crude appliances. Turning from his barbering and wig-making, Arkwright learnt all he could about spinning and in 1769 took out the patent which laid the fortunes of himself and hundreds of others. The novel feature in his new spinning machine was the use of several pairs of rollers for drawing out the cotton fibres before they were spun, and this principle is applied on a very extended plan to-day. But he was more than an inventor, for he envisaged and put into action the plan of setting out in ordered fashion in one building machines, different in character and design, and driven by mechanical power, arranged to secure a continuous flow of material from the raw state through the various processes until it emerged a finished yarn. This idea of a complete cotton-spinning factory shows genius of a high order and Arkwright may be regarded as the 'first master cotton spinner'. Arkwright, it may be added, died at Cromford, Derbyshire, on August 3, 1792, at the age of fifty-nine years. His portrait by Wright is in the National Portrait Gallery.

Cancer Research at Nottingham

AT the annual meeting of the Court of Governors of University College, Nottingham, on December 15, under the presidency of His Grace the Duke of Portland, it was reported that a scientific research fellowship had been founded through the generosity of Mrs. Massey and Mrs. Massey Stewart. The purpose of the fellowship is to develop the physical methods for the diagnosis and cure of cancer. The Council appointed to this fellowship Dr. L. A. Woodward, who has had a distinguished career at Oxford and Leipzig. The local branch of the Imperial Cancer Campaign has made contributions of £500 for the purchase of additional instruments required and £50 to cover travelling expenses in connexion with the investigations. Accommodation has been found for the fellow in the Department of Physics, and the general equipment and facilities of the Department will be available for his use. The assistance of a biochemist in Dr. Woodward's work has been secured by the appointment of Dr. H. H. Barber, towards whose salary the Nottingham branch of the British Empire Cancer Campaign is contributing a sum of £100 a year for a period of three years in consideration of this assistance. A Joint Cancer Research Committee has been set up, consisting of the Principal, the heads of the Departments of Biology, Chemistry and Physics, and Dr. F. H. Jacob, Dr. R. G. Hogarth and Dr. A. M. Webber as representatives of the local branch of the British Empire Cancer Campaign.

Science and War

IN a speech delivered in the House of Commons on November 10, which has been reprinted by the *New Commonwealth* under the title "The Warning", the Right Hon. Stanley Baldwin deals with the moral and ethical consequences of the application of scientific discoveries or inventions to destructive purposes. Science has completely transformed the character and offensive powers of modern warfare. To the air attack there is no possible defence save in counter-attack, and aviation affords an outstanding example of an instrument of war the consequences of which are so terrible and deadly that the safety of mankind lies in the renunciation of its use. So far as the air is concerned, Mr. Baldwin agrees that only the abolition of flying offers any prospect of complete disarmament. Prohibition of the bombardment of the civil population and reduction of the size of aeroplanes are suggestions that are unlikely to stand the stern test of war. The abolition of flying is, however, an inconceivable step. Mankind has never yet consented to forego a new power which he has once claimed and the practical question which remains is the use to be made of this new power. Mr. Baldwin suggests that a thorough investigation of the problems involved in the international control of aviation is called for, apart altogether from the possibility of abolishing all air forces. Scientific workers should be among the first to respond to the moral appeal underlying Mr. Baldwin's speech, that with the winning of new powers for mankind there should be won also a finer sense of moral responsibility and a determination to oppose the prostitution of such powers to base purposes. Only such a sense of values and of responsibility on the part of every individual citizen can save mankind from the destruction and disorder which seem the inevitable outcome of the present state of international relations.

The Royal Dublin Society

IT is recorded in the *Irish Times* of December 2 that Viscount Powerscourt has taken over the office of president of the Royal Dublin Society, in succession to Prof. J. Joly, whose term of office (three years) has come to an end. In the course of his Lordship's remarks, Lord Powerscourt, who is a leading member of the Agricultural Section of the Society, stated reasons for believing that the policy of the present governing body in Ireland must result in very grave effects upon the agricultural work of the Society. These fears are supported and very strongly emphasised by Dr. Bohane, the official director of the Society, in the *Irish Times* of December 3, whose remarks are mainly directed to financial considerations connected with the agricultural work of the Society. We are informed by Prof. Joly that the scientific work of the Society must also suffer seriously, seeing that the Society expends considerable funds in support of scientific research and on the publication of its *Scientific Proceedings and Transactions* as well as on fees paid to experts who lecture upon scientific subjects in various rural districts of Ireland. The Irish Radium Institute—which is legally affiliated to the Society—must also suffer, considering that the distribution of radium emanation devolves upon a senior and highly responsible member of its paid scientific staff. Those who wish for a full account of the Society's work at the present day will find it detailed by expert members of the Council in a volume issued recently in commemoration of the two-hundredth anniversary of its work for the prosperity of Ireland.

Statistical Method of Control in Industry

AN important aspect of the part which statistical method may play in industry in the improvement of the production process and in increasing efficiency in the fitting of supply to satisfy the wants of the consumer was discussed on December 20 at a meeting of the Royal Statistical Society, when Dr. E. S. Pearson contributed a paper on the statistical control of quality in mass-production industry. Whether the manufacturer is concerned with the tensile strength of malleable iron, the length of life of lamps, or the durability of cloth, he cannot succeed in producing exactly the same article again and again. Quality must, in fact, be expressed not only by an average but also by some measure of variation about this average. Yet if this is so, it is also important that there should be uniformity in this variation. For example, if the variability in the length of life in electric lamps can be reduced below a certain level, this may be of little value to the ordinary householder; but a large-scale consumer such as a borough council may then find it a more economic proposition to

renew all its street lamps after a fixed number of hours of burning than to wait till each lamp burns out, and then send a man to replace it. For a number of years individual firms have here and there made use of statistical theory in laying out efficient research programmes to improve the quality of production or to establish sampling plans to reduce the cost of inspection. But it is only in the last few months that an attempt was made to organise concerted action, when the British Standards Institution appointed a small committee to investigate the problem from the point of view of standardisation and specification. Direct contact between the industrialist and the statistician is of first importance. The former has not hitherto fully realised the potentiality of the statistical tool, while the latter has not understood the lines along which theory could be most helpfully developed.

The Roman Wall in Scotland

AT the Friday evening discourse on December 16 at the Royal Institution, Sir George MacDonald discussed the Roman Wall in Scotland. So far as its chances of survival were concerned, the Wall was unfortunately situated. Stretching, as it did, from Forth to Clyde, it ran, for the most part, through arable land and also traversed what was destined to become a great industrial belt. Nevertheless its remains are still considerable. The date of its erection was about A.D. 142, soon after the accession of Antoninus Pius, and it is quite certain that it was abandoned before the end of the century. Soldiers say that, as a piece of military engineering, the line which it followed was admirable, much superior to that selected for the Wall of Hadrian. The barrier consisted of three main elements—a rampart, a ditch, and a military road—and there were nineteen supporting forts, planted at intervals which averaged two miles in length. Despite its excellent construction, the road has been destroyed almost everywhere. On the other hand, the ditch, which was usually about 40 ft. wide and 12–15 ft. deep, has left an enduring mark. Even where it has been entirely filled in, digging will always reveal its position. Within the last twenty years its course has been determined for practically the whole 37 miles of its length, and this will be noted on future issues of the Ordnance Survey maps. A group of seventeen inscriptions, unique in the Roman world, yields extremely interesting information as to the distribution of the work among different bodies of legionaries. The purpose of the Wall is often misunderstood. What it contemplated was not a state of war, but a state of restless peace. Excavation has proved that the forts were twice evacuated and twice restored before the final abandonment, and has also brought us to some extent into personal touch with the men who maintained the *pax Romana* in North Britain in these troublous days. They were not Romans, in the strict sense of the term, but a motley crew, levied chiefly in Gaul and the Low Countries, having Latin as a common language and welded into a unity by iron discipline.

A New Academy of Sciences in Western China

THREE years ago there was organised in the Little Gorges near Chungking of Szechuan province an Academy of Sciences of Western China. This institute is supported primarily by private contributions. It has now an annual budget of 40,000 Mexican dollars. Research and survey work along the lines of geology and biology will be pursued in the Academy. At present, with the help of Dr. H. H. Hu, director of the Fan Memorial Institute of Biology at Peiping, a herbarium and a botanical garden have been established by the Academy, with the view of exploring botanically all parts of that vast province and eastern Tibet, and collecting seeds, cuttings, and bulbs, etc., for planting in the botanical garden. It is intended shortly to establish a nursery where seeds and bulbs will be provided for sale or exchange. For example, the collector was instructed to collect seeds of *Rehderodendron*, a new genus of three species of ornamental trees of Styracaceæ, recently described by Dr. Hu. Seeds of other interesting and ornamental plants will also be collected. The Arnold Arboretum of Harvard University will be the first botanical institute in the United States of America to share a part of this collection. This year two parties have been sent out by that institute to collect herbarium specimens and seeds, one to eastern, another to south-western Szechuan. The latter is exploring the bordering districts along the Szechuan-Yunnan-Tibet borderland. In the winter the collector will bring herbarium specimens and seeds to the Fan Institute for study and identification, as that institute has a large herbarium and a large botanical library, and furthermore a unique collection of some 17,000 photographs of the type-specimens of Chinese and other Asiatic countries taken in various European herbaria.

"Terrestrial Magnetism and Atmospheric Electricity"

THE September issue of *Terrestrial Magnetism and Atmospheric Electricity* forms a memorial number in honour of the late Dr. Louis A. Bauer, who founded the journal in 1896 and edited it almost until his death early this year. It contains two admirable portraits of Dr. Bauer. The number is of unusual length, containing 220 pages, and (besides subsidiary matter) thirty-seven articles by authorities on terrestrial magnetism and electricity from all over the world. Some of these are of unusual interest, and among them may be mentioned those of Adolph Schmidt, J. Bartels, and L. Vegard. Schmidt deals with the secular magnetic variation, and shows that many of its larger features can be explained in a simple way as due to the rotation of a component of magnetic polarity, about an axis through the points where the Greenwich meridian crosses the equator, so that the poles of this component move in the meridians of longitude 90° and 270°, the complete rotation taking about 480 years. This simple conception explains the main features of the secular variation but does not agree so well with the long-continued decline of the earth's magnetic moment during several decades past. The article by Bartels

is on statistical methods for research on diurnal variations, and contains both important conclusions and interesting suggestions for future work in this difficult field.

THE paper contributed by Prof. L. Vegard is a brief account of an investigation of the temperature of the auroral region by the use of the rotational series of the negative nitrogen bands, shown on auroral spectra obtained by long-continued intermittent exposures over several weeks or months. The results obtained in two different ways agree in giving the value of 240°K. This is much lower than the high temperature for this region first proposed by Lindemann and Dobson on meteoric evidence, and confirmed by the abnormal propagation of sound, by reflection at a height of about 40 km. In this connexion, Vegard mentions experiments he has made tending to show that the laws of propagation of sound at low densities are different from those that apply at normal densities. The paper is an interesting contribution to a controversial subject. Another interesting paper, by Prof. V. F. Hess, reviews the present state of knowledge concerning cosmic rays, mentions the co-operative scheme of work started on his initiative in order to examine whether the irregular fluctuations of the rays occur simultaneously in different places, and gives some preliminary results of the work of his cosmic ray observatory on the Hafelekar ridge, near Innsbruck.

Exploration of the Upper Atmosphere

THE International Commission for the Exploration of the Upper Atmosphere has recently published the collected results of upper air work done during 1924, under the title "Comptes Rendus des Jours Internationaux, 1924". As in the case of the first and pioneer volume of the kind, for 1923, the compilation has been made under the supervision of Sir Napier Shaw, honorary president of the Commission; the 1924 volume has unfortunately been delayed by his illness, and by financial difficulties. The latter have been lightened by the use of the Replika process in the production of the volume, the price of which is 45*s.*; the later volumes (of which that for 1925 has already appeared, under the title "Ergebnisse der Aerologischen Messungen, 1925"), are being published by Prof. Hergesell, president of the Commission, at the regrettably high price of 60 gold marks. The present volume is in two parts, one containing tabular details of the ascents of sounding balloons, together with synoptic charts for the international days, and the other containing 'tephigrams' representing graphically the results of individual ascents.

Rainfall and Water Supply

IN an article by F. J. Garland entitled "Rainfall and Water Supply" in *Progress and the Scientific Worker* for September and October 1932, stress is laid on the importance of the work of the voluntary rainfall observers whose records supply a very large proportion of the material for the annual volumes of "British Rainfall", the old-established publication of the British Rainfall Organization now compiled by the Meteorological Office. The article contains interesting facts about springs and artesian wells, and some particulars about the practical side of the engineering problems involved in conveying water to distant towns from catchment areas. On these subjects the writer is on his own ground, but when he passes to purely meteorological matters connected with rainfall, some very inaccurate statements are made. Thus, he says (p. 49) that the greatest recorded rainfall in England in 24 hours may be taken to be about three inches. The annual volumes of "British Rainfall" show however that falls greatly in excess of three inches occur in most years; that 9·56 in. fell in one day in 1917 at Bruton, Somerset, and 9·40 in. at Cannington once in 1924. The incorrect statement is also made that there is no satisfactory record of the amount of rain that fell during the Louth cloudburst of May 29, 1920, whereas, thanks to the records of voluntary observers, enough information was available for the rainfall to be mapped by means of isohyetal lines for the whole area of the storm, and this information is available not only in "British Rainfall" for that year, but also in the report of the special investigation undertaken by the Meteorological Office (Professional Note, No. 17, of the Meteorological Office. London: H.M. Stationery Office).

Scots Pine Timber

BULLETIN No. 15 (Dec. 1931) of the Forest Products Research Laboratory deals with a detailed analysis of "The Timber of Home Grown Scots Pine (*Pinus sylvestris*)". The primary considerations in connexion with the utilisation of home grown Scots pine, the resources of which timber in Great Britain were so depleted during the War, are the general grade of the timber and its mechanical properties. The investigations which have been undertaken at the Laboratory indicate that the home grown timber in different localities varies considerably in weight, and ranges from 25 to 45 lb. per cub. ft. at a moisture content of 12–15 per cent. The darker colour of the heart wood, which is an indication of the durability, is more marked in the home grown than in the imported timber, while the percentage of heart wood is dependent on locality and age. The average rate of growth of the timber in the four consignments examined varied from 4 to 23 and the average of individual consignments from 7 to 12 rings per inch. The bulletin deals in sections with structure, seasoning, mechanical and physical properties, antiseptic treatment, working and utilisation, and pests of the species. One of the problems facing the newly formed plantations of pine in Great Britain is to find or create a market for the small material which will come out in the early indispensable thinnings; while, it is pointed out, to produce best quality timber the time must be given to obtain at least 12 rings to the inch radius, and for lower grades at least 9 rings per inch are necessary. Straight-grained timber, as free from knots as possible, is demanded by the markets.

Illuminating Engineering

THE paper on the electric lighting of buildings read by A. B. Read and Dr. J. W. T. Walsh to the Institution of Electrical Engineers on November 3 illustrates the change that has come over the art of illumination during recent years. Originally the aim was to provide as much light as possible for the very limited consumption of energy available. Happily, owing to the great advances made in the means of light production, engineers are no longer trammelled by tradition and new and daring experiments are being made in illuminating engineering similar to those made possible in architecture and decoration, due to the use of new constructional methods and materials. The second part of the paper deals with the engineering and physiological principles which govern design and gives a brief description of the new materials now available to the 'artist in light'. Architects now provide electric 'points' on their plans not for 'a light of some sort' but for a fitting in character with the room. Lighting by electricity can be done in many ways. It can be used to enhance the restful atmosphere of a place of worship, dignify a great public building, serve as a decorative element in a small house, or bring sparkle and gaiety to a restaurant. The latest development in light production is the gaseous discharge tube. The use of various mixtures of the rare gases provides a wonderful range of hues in the light available. The efficiency of the lamp also has been greatly improved. It gives three or four times as much light as the ordinary tungsten filament gas-filled lamp. The authors conclude by discussing the effects of glare, contrast, shadows and colour. The paper proves that the task of the lighting engineer is a difficult one.

Report of the Strangeways Research Laboratory

THE Trustees' Report for 1931 on the Strangeways Research Laboratory, Cambridge, records as the outstanding event of the year the extension of the laboratory, made possible by a bequest of £5000 from the late Sir Otto Beit, and refers to the additional connecting links between the laboratory and the biological departments of the University which afford opportunities for valuable collaboration, for example, in zoology, nutrition and radiology. A résumé of the work in progress shows that Dr. H. B. Fell and her colleagues are carrying out with skilful technique investigations of great interest on tissue culture. Reference is made to the better results in the study of osteogenesis due to improvements in technique. Of the other work recorded we note Dr. P. D. F. Murray's studies on the development *in vitro* of the primary red blood corpuscles of the chick. Portions of fowl embryos removed from the egg after periods of incubation ranging from 1 to 18 hours were cultivated in a fluid medium composed of serum and embryo extract. Red blood corpuscles developed in all the cultures made from the posterior half of the primitive streak at the stage immediately preceding the formation of the head-process, but portions of the anterior half, although differentiating into central nervous system and somites, formed no blood. All the stages in erythrogenesis could be followed in the living material. The first sign was a thickening in the tissue; the cells of this thickening diminished considerably in size and displayed great mitotic activity. Eventually they lost their adhesiveness, formed loose groups in the tissue or fell into the culture medium as a cloud of free erythroblasts in the cytoplasm of which hæmoglobin began to develop.

Industrial Models at Hull Museum

THE crushing of linseed and rape seed obtained from the plants of northern Europe has long been a staple industry at Hull, which now claims to be the largest oil-mill centre in the world. In view of this, it is interesting to learn that the Museum contains a remarkable series of models of seed-crushing plant illustrating both old and new methods. The models were described in the *Model Engineer and Practical Electrician* in April last and the articles have now been published in pamphlet form as Hull Museum Publication No. 176. The models have been made by Mr. W. Marshall, who began his connexion with the industry as a blacksmith in 1869, rose to be manager of some of the largest mills and became a manufacturer of oil-mill plant. The beginning of the oil-seed industry is lost in the mists of antiquity but in certain parts of the world to-day very primitive plant is used. From these primitive devices came the lever press, the wedge press and the screw press, and in more modern times the hydraulic and steam power presses. These are all illustrated by Mr. Marshall's models, which are described in the pamphlet.

Publications of the University of Bombay

IN order to encourage research among teachers and students, the authorities of the University of Bombay have decided to issue a periodical publication, which will contain communications from members of the university and others dealing with research in the subjects of the University curriculum. The *Journal of the University of Bombay*, as the publication is to be called, will appear six times in each year, two of the parts being devoted to history, economics and sociology, two to arts and law, and one each to the physical sciences and the biological sciences. In addition to the original articles, there will be reviews of books, abstracts of academic theses and notes on current topics. The first issue, which has recently appeared, covering history, economics and sociology, contains several communications dealing with points in the history of sixteenth century India, India's trade and commercial relations, Indian art and sociology, the bearing of certain traditions on the origin of Konkan Brahmins, and articles of a more general character on trade unions and the League of Nations. Especially noteworthy is a lecture delivered in Bombay by M. Elie Faure on the interpretation of Indian art, in which it is suggested that a meeting-ground for Europe and India might emerge from their common inheritance from Greece. There is also an obituary notice of the late Sir Patrick Geddes, which does full justice to his work for India.

Infra-Red in Photomicrography

THE photography of small insects by transmitted light has hitherto been complicated by the necessity of employing screens transmitting only the red end of the spectrum, if detail of both body and wings is to be secured on the same plate. Recent improvements in the sensitising of plates to infra-red enable much darker screens to be used with relatively shorter exposures. An interesting example of this has recently been given by Mr. A. E. Smith (*Watson's Micro. Rec.*, No. 27) who publishes a photograph of a phorid fly in which the venation of the wings and the structure of the external genitalia are shown at the same time as the minute detail of body armature. The exposure of only five seconds through the almost opaque Ilford infra-red screen is a remarkable tribute to the speed of the plates, which quite evidently open a new field for the photomicrographic worker in all subjects.

Memorial to Prof. W. D. Halliburton, F.R.S.

ON December 17, Sir F. Gowland Hopkins unveiled a plaque which has been placed in the Halliburton laboratory of physiology at King's College, London, in memory of Prof. W. D. Halliburton, who was professor of physiology at the College from 1890 until 1923. When Prof. Halliburton was appointed, the laboratory was on the Embankment in small and badly lit rooms where Ferrier and Lister had worked. Yet, by his enthusiasm, he managed to attract many young physiologists to the College. The present laboratory is the result of his great efforts during his tenure of office as professor of physiology. Prof. Halliburton was elected a fellow of the Royal Society in 1891 and died on May 21, 1931, aged seventy years.

Duddell Type Oscillographs

THE Cambridge Instrument Co., Ltd., has issued a new list of oscillographs developed from the Duddell type (List No. 118). As usual in the catalogues of this firm, there is a valuable discussion of the design of the instruments, but the present list is noteworthy for the large number of examples of their use. These include the study of wireless 'echoes', of speech wave forms and of mechanical vibrations in turbine blading. In view of the modern development of large units in electrical engineering, there is a particular interest in the installations for investigating short-circuit and circuit-breaking phenomena and in the reproductions of very beautiful oscillograms obtained by their use.

Christmas Lectures at the Royal Institution

THE Christmas Lectures at the Royal Institution are to be given this year, starting on December 27, by Prof. Rankine. Prof. Rankine, who is president of the Physical Society, has carried out laboratory researches on the determination of the sizes of numerous gaseous molecules, as deduced from measurements of viscosity. During the War he investigated the possibilities of transmitting speech by light, using the selenium cell, and invented an instrument for this purpose, the photophone. In recent years his scientific work has taken him farther afield. He has been concerned in the latest developments of the science of geophysics, particularly in regard to its use in prospecting for minerals, including oil, and has made expeditions to Persia and Australia in connexion with this work. The subject of Prof. Rankine's lectures, 'The Round of the Waters', is full of possibilities. The subject lends itself to experiment in a great variety of ways, and this, the one hundred and seventh course of Christmas Lectures, should certainly not be wanting in interest and instructiveness.

Announcements

AT a meeting of the Royal Academy of Belgium held on December 15, Prof. P. Zeeman, professor of experimental physics in the University of Amsterdam, and Prof. T. Levi-Civita, professor of rational mechanics in the University of Rome, were elected foreign associates of the Academy.

THE Hopkins prize for the period 1924–27 has been awarded by the Cambridge Philosophical Society to Prof. G. I. Taylor, Yarrow research professor of the Royal Society, for his researches on hydrodynamics and on the deformation of crystals; and the prize for the period 1927–30 to Prof. P. A. M. Dirac, Lucasian professor of mathematics in the University of Cambridge, for his researches on the theory of quantum mechanics.

WE have received the report of the Victorian Bush Nursing Association for the year ended June 30 last. This Association, of which Sir James Barrett is secretary, provides trained nurses and other requisites for sick and injured persons in country towns and districts. It is run on a co-operative basis, a householder paying a small annual subscription, usually £1, and has 65 nursing centres and 29 cottage hospitals. Maternity and child welfare are important branches of the work. In spite of the financial stringency in Australia, the Association had a credit balance of £1,900 at the end of the year. Full reports are given of the activities in the various centres.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A male junior assistant metallurgist for the Royal Small Arms Factory, Enfield Lock, and a male junior assistant chemist at the Royal Gunpowder Factory, Waltham Abbey—The Principal Clerk, Central Office, Royal Gunpowder and Small Arms Factories, Enfield Lock, Middlesex (Jan. 7). An assistant in the Department of Manuscripts and Records of the National Library of Wales—The Librarian, National Library of Wales, Aberystwyth—(Jan. 16). A University professor of physics at Birkbeck College—The Academic Registrar, University of London, S.W.7 (Feb. 10). A director (professor) of the Research Laboratory in Botany at the University of Madras—The Registrar, University of Madras, Triplicane, P.O. (April 1); further information from the High Commissioner for India.

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

'Protective' Adaptations of Animals

WITH regard to recent correspondence in NATURE[1] following an article based on my paper on the effectiveness of protective adaptations,[2] I would remark, in the first place, that since neither Prof. Poulton, Prof. Huxley, and Mr. Nicholson appears to have seen my paper, their criticism should have been deferred. As to the points raised, I offer the following suggestions:

Prof. Poulton's main point would seem to be expressed in the following quotation: "To search with the compound microscope for butterfly wing-scales scattered through the contents of 80,000 avian digestive tracts would be a serious business, and if it had been accomplished I venture to believe that far more positive results would have been obtained." On p. 6 of my paper the use of compound microscopes in making all stomach examinations is noted. The alleged difficulty of identifying remains of adult Lepidoptera in bird stomachs is discussed on p. 59. Instead of encountering difficulty in recognising lepidopterous remains, I may say that when Lepidoptera have been eaten, the fact usually is evident to the practised eye at a glance due to the fuzzy felted appearance of the stomach contents caused by the distribution of hundreds of scales throughout the mass. The story is just as plain as that told by the contents of a killing bottle in which other insects have been carried with Lepidoptera; there seem to be scales enough to cover everything. If only a few scales were present, they might be missed, but in such cases in all probability the wing membranes with their characteristic venation, or the antennæ, head, or some other diagnostic part would be present and identifiable.

In 1912 I published the statement that remains of butterflies were found in only 5 out of 48,000 bird stomachs, while the 1932 paper records 87 from some 80,000 stomachs. Prof. Poulton now says that I attempt no explanation or defence of the earlier figures; on p. 60 of my paper, it is stated that all save 18 of the records pertain to a single bird, the pigeon hawk, and that the specimens of this hawk were taken at a point in a migration path of butterflies. The instance is a striking one supporting my general thesis as to the great effect abundance and availability of prey have upon choice of food by birds.

As a matter of fact, some of the other records also were from other hawks collected at the same locality (Fisher's Island, N.Y.), so that the 18 instances of butterfly captures by birds under supposedly normal conditions is still further reduced and the not alarming disproportion of 18 records for 80,000 to the 5 for 48,000 stomachs previously reported is correspondingly lessened.

Prof. Huxley's ship illustration, whether paralleling Nature or not, does not have his own confidence as he says, "Even if the proportionality [of destruction relative to type] were exact, it would have little significance." He pins his faith on the necessity of adaptations and says, "In general, the fallacy is that of forgetting that no species of organism could exist which was not a bundle of adaptations."

As to organisms necessarily being adapted, we find in almost every environment species of such diverse 'adaptations', if the use of that too meaningful term is permissible, as to prove that particular 'adaptations' cannot have been essential to survival. Huxley's picture of an organism that could not survive as one "conspicuous in colour and in habits, sluggish, palatable, juicy and soft, and with low fecundity" is in fact realised in some of the spiders—nevertheless they survive.

Quoting Prof. Huxley again, "The fact that 'some birds' . . . eat ants freely does not imply that ants are not rejected, relatively or entirely, by most birds." Ants are not rejected either relatively or absolutely by any potential predators. As nearly as may be, they are eaten by every kind of predator and freely by most of them.[3]

As to Mr. Nicholson's criticism, it appears to have little bearing. He says, "While it is evident that the book contains a vast array of statistical data on the contents of birds' stomachs, no mention is made of a similarly exhaustive survey of the food that was available to the birds, and, in fact, it is inconceivable that such a survey could be made adequately." Like my other critics, Nicholson had not seen my paper, hence does not know of the effort that was made in it to indicate the relative abundance of available prey. If he really believes that this information is unobtainable, then he should not criticise me for not presenting it.

Selectionists in an attempt to advance their cause have habitually appealed to unknown factors, and cited examples from largely unknown faunas (for example, of the tropics), to which doings Nicholson's remark, "such work can throw no light upon the process of natural selection", exactly applies.

The remainder of Mr. Nicholson's paper seems to have little application to mine. Nicholson is a mutationist, while the theory of natural selection during most of its history has relied chiefly on the preservation of small variations. As most critics of the theory have remarked, it is inconceivable that an initial slight variation in a favourable direction could have selective value. This is a fatal objection to old style natural selection theories all along the line. Whether there are enough 'large variations' or mutations to satisfy theoretical demands is another question which need not be debated here.

In general, as a reply to all critics, I would say that the importance of predators in controlling animal populations has always been over-rated. The grand factors are meteorological, and these as well as some of the other checks are by their nature barred as selective agents so far as 'protective adaptations' of the kind under discussion are concerned. This fact, in addition to consumption by predatory forms being very closely proportional to population, indicates that selection, if it exists at all is a force so weak that it cannot have guided the course of evolution so as to account for the structure and characteristics of all existing organisms in detail, which is practically what is attributed to natural selection by its extreme proponents.

I would emphasise that natural selection is still merely a hypothesis, and a vigorously challenged one at that. In 1894, Alfred Russel Wallace said: "It is of course admitted that direct proof of the action of Natural Selection is at present wanting,"[4]

and in 1932, Hugh B. Cott still has to admit with regard to the selectionist explanation of 'protective adaptations', "The hypothesis is of a sort which is incapable of proof."[5]

Darwin's great service was in pointing out the apparent probability of evolution, and we should not be considered as failing in respect if we doubt that he formulated a satisfactory explanation of the process. It would have been miraculous if Darwin had been able to anticipate the developments of more than a half-century of the most intensive biological investigation the world has seen. Hence we should not be surprised that all of the main points in his theory to explain evolution, namely, (1) the severity of the struggle between organisms for existence, (2) the preservation of individuals possessing slight favourable variations, (3) the inheritance of these variations, and (4) the similarity of natural to artificial selection, in the light of present day information must all be radically challenged.

I hope sometime to assemble and publish the notes on these matters that I have been making for years. For the present I would remind supporters of selectionist doctrine regarding protective adaptations that they are only bolstering a single pillar of a structure, the whole of which is adjudged by many biologists as doomed to collapse.

W. L. McATEE.

[5] *Proc. Zool. Soc. Lond.*, Pt. II, p. 492; 1932.

IN his review in NATURE[1] of a publication by W. L. McAtee, entitled "Effectiveness in Nature of the so-called Protective Adaptations in the Animal Kingdom"[2], "B.P.U." apparently expresses agreement with that author in interpreting what he believes to be 'proportional predation' as evidence of indiscrimination in the choice of food by birds and other predatory animals. Mr. A. J. Nicholson has pointed out that the examination of birds' stomach contents, by itself, can give no evidence of proportional predation.[3] There is, however, another aspect of the subject to which I would direct attention.

Even were it demonstrated, as McAtee claims, that birds prey upon animals approximately in proportion to their numbers, it is difficult to follow him when he says "This means that. . . . predation takes place much the same as if there were no such thing as protective adaptations". McAtee's figures have reference to the various groups of food-animals eaten by "a wide range of species of all the families of birds occurring in the region". The food of these is considered collectively, and herein lies the fallacy in his argument.

This collective treatment of data takes no account of discrimination in the choice of food by *species*. I am not aware that any exponent of the selection theory claims for 'protected' animals immunity from attack. Every zoologist knows that specially defended insects suffer predatory assault. For example, ants have hosts of enemies, including many forms which eat practically no other food, such as Agamid lizards, some tree frogs and toads, woodpeckers, tamanduas and pangolins, besides numerous more casual predatory forms. Whether these so-called 'protected' insects are preyed upon in proportion to their numbers is still open to question. But the real point at issue is to determine whether this proportion—whatever it may be—would remain unaltered in the absence of the adaptations the effectiveness of which McAtee attempts to disprove. In other words, are these adaptations effective against *some* enemies? To this question McAtee's figures provide no answer.

The best method of approaching the problem is by the comparative examination of the stomach contents of predatory forms living in the same habitat, where the same food is available for different species. Viewed in this light, marked differences are observed in the food of different species in relation to that actually available: and selective discrimination, so vigorously denied by McAtee, is found to be the rule rather than the exception.

In NATURE of November 5, Mr. B. P. Uvarov[4] pays me the compliment of referring to a paper of mine, in which he states I have found "that ants constitute more than 90 per cent of the food of frogs". This statement refers accurately to four of the seven species of tree frogs examined by me. In this paper[5] is presented a considerable body of evidence of discrimination in the choice of insect food by tree frogs. In a more recent detailed investigation of the food of British batrachians I find strong evidence in support of this view. This is not the place to go into details which it is hoped will be published later. But it is pertinent to mention here that in a collection of frogs and toads taken both in the same habitat and under uniform conditions, the stomach contents of the two species differ markedly. Thus in 17 frogs and 45 toads collected on the heath-land association of Land's End during the past summer, the following striking differences in food animals were noted:

Food	*Rana temporaria* (per cent)	*Bufo vulgaris* (per cent)
Mollusca ..	24·8	0·6
Lepidoptera ..	13·4	2·4
Diptera ..	9·1	0·9
Formicidæ ..	0·4	41·4

These figures do not look like 'proportional predation'. Rather do they illustrate how a comparative study of predatory habits in insectivorous animals points to selective discrimination in the choice of food.

Nov. 29.—It remains for me to add that the above was written before the Editor let me see a proof of Mr. McAtee's reply to his critics. Considerations of space forbid comment here upon more than one point raised in his present letter.

With reference to the protective adaptations of ants, I would add to the data given above that in a careful examination of the alimentary tracts of 238 frogs and toads (collected between June 7 and October 30 in different habitats in Cornwall, Gloucester and Sussex, and at almost every hour of the day and night), the analysis of some 9,000 food-animals works out in reference to ants as follows:

4,103 ants were recovered from 126 out of 148 toads examined:

7 ants were recovered from 6 out of 90 frogs examined.

In the face of facts such as these, Mr. McAtee would do well to reconsider his sweeping assertion that "Ants are not rejected either relatively or absolutely by any potential predators".

The New Infra-Red Band System of the CO Molecule

THE transition of the CO molecule from the upper electronic state of the Hopfield-Birge absorption bands to the upper level of the Cameron bands, gives rise to a system of bands degraded towards the red, and extending from the infra-red region to about λ5660 A. These new bands, as they were called, were photographed by Asundi,[1] who also gave their gross vibrational analysis. On Asundi's plates the bands showed a diffuse multiplet structure. Measurements were made only on the first and the last heads.

It does not seem to be generally known, however, that McLennan, Smith and Peters[2] previously recorded the same bands as a series of triplets, using different conditions of excitation. The wave numbers of the first and the third head in each of the triplets agree closely with those of Asundi's, and in addition, measurements on the second head are also available. Making use of the equation given by Estey[3] for the new bands, McLennan's results fit in well in the expression:

$$V = \begin{matrix} 9325 \\ (9284) \\ 9233 \end{matrix} + (1173n' - 9n'^2) - (1726{\cdot}5n'' - 14{\cdot}4n''^2)$$

The value (9284) in the above equation, for the electronic energy of the second band-head, is obtained from the triplet separations as observed by McLennan.

In addition to all the transitions recorded by Asundi, those corresponding with (9, 2) (10, 2) (11, 2) (10, 3) and (11, 4) are to be noticed in McLennan's data, but transitions (2, 0) and (4, 1) are missing.

Johnson[4] and Asundi[5] put forward the view that the final level of these bands which is the same as the third positive and the associated bands is a quintet level, while Birge[6] and Mulliken[7] hold that it is a triplet one. It is of interest therefore to note that in the light of McLennan's results, the level appears to be a triplet one, unless some bands too faint for observation were missed. The unweighted mean of the triplet separations in the direction of the degradation of the bands is 37 and 46.

Absorption Spectra of Metallic Colloidal Solutions, and Emission and Absorption of Metallic Films

Absorption of solutions and films. The absorption curve of films of silver has been recently published by Mohler[1]; and we have recently published the absorption curves of colloidal solutions of silver and gold.[2] The absorption curves of the colloidal solutions of silver and of the films of this element are almost exactly coincident, as may be seen on Fig. 1, where the axis of the ordinates for curve I (solutions of colloidal silver) shows the values of log $I/I_1 = \alpha d$, and for curve II (silver film at a temperature of 300° K) the values of log $J/J_0 = (4\pi nkx/\lambda)$ log e. The agreement between these curves confirms Mie's theory[3] that metallic colloidal particles have the same

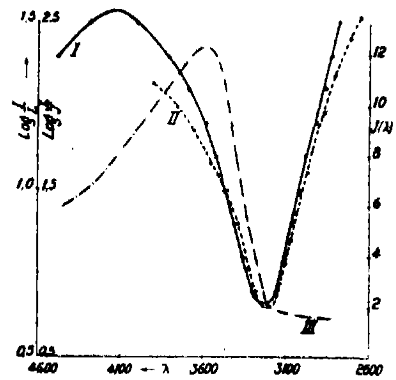

FIG. 1.

optical properties as a macroscopic mirror of the same substances.

Emission and absorption of the films. The films of tungsten, aluminium, beryllium, gold-calcium alloy, thorium and platinum bombarded with 7 volt electrons emit, according to Möhler and Beckner,[4] radiations similar in their intensity and in its distribution; the distribution of the spectral energy is constant between 6,400 A. and 2,400 A. Exceptions to this characteristic property are offered by copper,

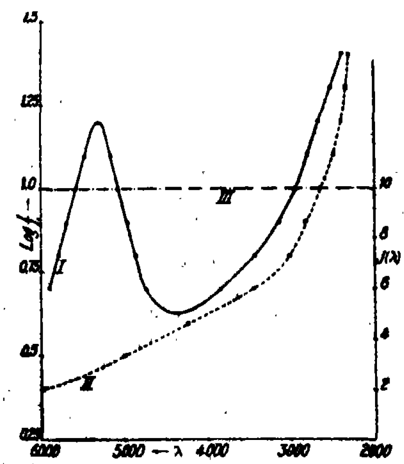

FIG. 2.

which shows a marked increase of emission in the red, and silver, which emits strongly between 3,600 A. and 3,200 A., the maximum emission being at this latter wave-length (Fig. 1, Curve III), which is near the maximum of absorption. In this instance there appears to be a relation between the maxima of emission and absorption. On the other hand, in the case of colloidal solutions of gold, there is no relation between the maxima of absorption and the spectra of emission of the films bombarded with electrons. In Fig. 2, curve I represents the absorption of colloidal solutions of gold (Bredig method), curve II

the same property for colloidal solution of gold (chemical method), and curve III is the emission of a gold film.

It would be of interest to determine whether the absorption curves of a metallic film are always identical with the absorption curves of the colloidal solutions of the same metal, as they are in the case of silver, with the view of ascertaining if Mie's theory is applicable to all metallic colloidal solutions; and also whether there is a correspondence between the characteristics of emission of the metallic films and their absorption, as happens in the case of silver.

Neutronic Equilibrium of Isotopes

IF the formation or disintegration under astronomical conditions of the chemical elements, including the light ones, is considered as going on continuously, it is obvious that for each kind of atom there must be present its parent and its succeeding element. It can be proved, however, that the emission of α-, β- or even H·-particles by disintegration, or the entry of the α-, H·-particles or the electrons into the nuclei, is unable to explain the existence of every isotope. For example, it is impossible to explain in this way the formation of Sc^{45} by decomposition of Ti^{46}, Ti^{50} and V^{51}, or by emission of an electron from Ca^{44}. Likewise it is impossible to explain the formation of Ti^{50} by means of the entry of α-, H·- or β-particles into the nuclei of any one known atom. The same phenomenon is found in many other cases among the non-radioactive elements. The same negative results are obtained by supposing that one atom decomposes into two other atoms, or that the two nuclei form a new atom. The existence of every kind of atom and of all isotopes can be explained without difficulty, however, by supposing that the atoms of different elements can emit or incorporate neutrons (Nr)—even under astronomical conditions.

$$O^{18} \rightleftarrows Nr + O^{17}$$
$$O^{17} \rightleftarrows Nr + O^{16}$$

This hypothesis leads to the conclusion that the concentration of each isotope depends on the velocity of formation or decomposition of the heavier isotope. The neutronic equilibrium among all the isotopes of one element was probably established in astronomical conditions of formation of elements. This equilibrium exists at the present time, however, although the non-radioactive elements are decomposed with extremely small velocity or never decompose.

The calculations carried out by the use of Aston's table of isotopes show that the emission of a neutron by an element is connected with a loss of mass equal to 0·9997 (average value for 18 isotopes). If we accept the data given by Chadwick for the mass of a neutron, its emission involves the introduction of a considerable amount of energy. If, however, the mass of a neutron is less than unity, this process is an exothermal phenomenon.

Time Determination

IN NATURE of October 29 appeared a letter on the above subject from Dr. de Graaf Hunter. A consideration of the geodetic literature of the last few years seems to indicate that he is a little pessimistic in his estimate of the errors likely to creep into longitude determination through the imperfect elimination of 'personal equation' by the modern transit micrometer.

Be that as it may, Dr. Hunter's proposed method of transit observation has much to recommend it. The general tendency in precise measurement, especially where it involves time as a measured quantity, is to make the whole thing automatic. This tendency needs to be combated or adopted guardedly because increased mechanism is undesirable in itself and because it frequently leads to unsuspected systematic error. For example, having occasion to use the rhythmic time signals both from Nauen and Rugby in connexion with gravity pendulum work, I found a systematic difference of 0·02 seconds in the estimation of this 2·1 hour interval by two observatories where good time-keeping is done. This means that the reaction of any automatic receiver to wireless signals depends upon some quality, possibly strength only, in the signals.

It will be noticed that Dr. Hunter eliminates one train of mechanism—the electrical contacts, the electro-magnetic pen and the chronograph—but inserts another and simpler mechanism—the electromagnetic shutter near the focal plane of the transit instrument. To this extent I think his method leaves something to be desired. The progressive flashing of the star in the field of view renders the observation almost precisely the same as that of the visual timing of a gravity pendulum. As a result of experience with the latter I formed the opinion that the electromechanical link in the chain—the so-called flash-box—was a weak one. In order to eliminate this link a chronometer (a Kullberg Mean Time instrument) was adapted to give direct flashes without the intervention of any electric current and without interfering in any way with its mechanism. A small plane metallic mirror was attached rigidly to the balance-wheel, which was then re-balanced in such a way as to give once more the excellent time-keeping for which the instrument had previously been noted. Although this arrangement gives four flashes per second, its use with an oscillator not differing in period by more than about one per cent from *n* times that of the wheel is found to be quite manageable. Further, the accuracy with which a single reading of a flash can be made lies between 0·001 second and 0·003 second, a figure which puts it out of court altogether as a possible source of error in determining the time of swing of the pendulum.

How, then, is it possible to preserve the spirit, so to speak, of Dr. Hunter's method of transit observation and yet do away with his mechanical shutter? Doubtless thinking on the same lines as he, I suggested in a report on longitudes to the meeting of the International Geodetic Union at Stockholm in August 1930 that if it were possible to communicate to the star image a small vertical oscillation the determination of time would be made with great accuracy by the unaided eye. The difficult judgment of *when* the image crossed a line would be replaced by the incomparably easier judgment of *where* it crossed.

As shown above, the comparison of the auxiliary

oscillator implied in this scheme with a chronometer or clock would be carried out to great accuracy with purely optical arrangements.

The practical details of my scheme present great difficulties but, surely, not insuperable ones.

Finally, I may add that the free gravity pendulum, which is the best time-keeper known over a few hours, has already been used on occasion to check the clock or chronometer during a longitude determination. Astronomers now prefer to place reliance on time-keepers rather than on star-places in determining the difference of longitude between two places.

Fourier Analysis and Vowel Curves

ATTEMPTS were made recently to apply the Fourier harmonic analysis to a collection of very large vowel curves traced off from a gramophone record through the courtesy of the Gramophone Company (His Master's Voice) of Hayes. One such wave in the actual size is reproduced in Fig. 1. The wave was first analysed by measuring 24 ordinates (12 harmonics). When a new curve was constructed from the results it showed scarcely the faintest resemblance to the original. The most important characteristics did not appear at all, and all the characteristics shown were erroneous. *Owing to the small vibrations, at least 200 ordinates* would have to be employed in order to produce any resemblance. This would require that number of schedules. At present the highest number for which schedules have been drawn up is 72 (published in my "Studies of Speech Curves", Carnegie Institution Publication No. 44). The work with 150 ordinates for a single wave would keep a person busy for several months.

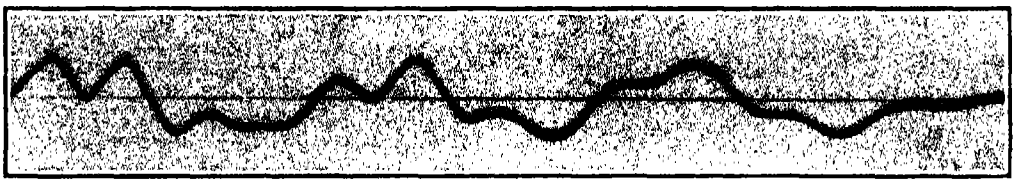

FIG. 1.—Part of a vowel curve traced from the words, "A day", from a phrase spoken by H.R.H. The Prince of Wales on November 11, 1927. Actual size.

Owing to the failure of measurements, the Mader harmonic analyser was then used. The point travelled over the curves and thus used every ordinate in producing the result. Even these curves were scarcely large enough to bring reliable results. The Henrici-Coradi harmonic analyser can be depended on to give reliable results when the wave is enlarged to 400 mm. horizontally. For large curves this would appear to be a satisfactory method except for one reason that will be stated later.

FIG. 2.—A few waves of the sound track of the vowel in a film record of 'hatch'.

Fig. 2 reproduces a few waves of the sound track of the vowel in a film record of 'hatch' made through the courtesy of R.C.A. Photophone Ltd., and Pathé, London. The curve shows fine details that cannot be brought out by a Fourier analysis on the basis of measurements with less than 500 measurements. Apart from the fact that schedules for such high numbers of ordinates do not exist, such an analysis of a single wave would probably require a year or so of calculation. Neither the Mader nor the Henrici-Coradi analyser can be used because the small waves are so steep that accurate readings cannot be made even in an enlargement. A decisive reason why no form of harmonic analysis can be used appears the moment *we observe that every vowel wave begins with a* strong upward jerk and fades away to almost nothing at the end just before the upward jerk of the next wave. The vowel wave is thus seen to have a strong decrement as one of its most important characteristics. A harmonic analysis does not provide for this decrement but uses it in giving false values to the assumed harmonic elements. A harmonic analysis of a decremental curve is necessarily erroneous. As pointed out previously[1] the curve of a vowel vibration represents a triple integration over the wave-length, the frequencies from zero to infinity and the *factors of decrement*. An analysis on this basis would give satisfactory results. A method for doing this does not yet exist. Any analysis that does not take the decrement into account gives erroneous results.

Another method of analysis[2] measures the apexes of the peaks and depths of the interior waves, and interprets the results as amplitudes of component harmonic sine waves. The method is superior to that of the Fourier analysis. It gives quite different results in that it provides for all frequencies and not the few harmonic ones. The method has been applied *with great success to larger non-decremental curves*, such as those of the number of travellers on a railway, drawings in a lottery, etc. It furnishes only erroneous results when applied to decremental curves and cannot be used for vowel analysis.

It is evident that an entirely new method must be found that shall satisfy the following conditions: It must provide for all frequencies between zero and infinity. It must provide for all factors of decrement that may be present. It must present its results in the form of numbers that have a useful meaning. It must not involve any assumption that the vibration is built up of simple sine movements. On the basis of sound tracks of the vowels, I am at present developing such a method and hope to have the result ready shortly.

The necessity for basing this and most other work concerning the physics of sound on sound tracks arises from the fact that the requirements of the film industry have produced a method of recording of very great accuracy. A comparison with the vowel

curves obtained by other means shows that they all lack the finer details that appear in the sound tracks and that all except a very few are so distorted that they can scarcely be said to be vowel curves at all. Of all the previously published vowel curves, only those obtained from gramophone records by myself and the Gramophone Company, those obtained by Miller with an oscillating mirror, those of Crandall with a special oscillograph, and those of Gemelli with a cathode ray oscillograph, resemble those in the sound tracks; even these lack the finest details.

Just Intonation

IF the tones C and the seventh harmonic of $A\flat$ are sustained together in the ratio 5 : 7, the two chief resultant tones are $A\flat$ and $E\flat$, the four tones together giving the true form of the accord known as the German sixth, 2 : 3 : 5 : 7, expressed in cents by the numbers 814, 316, 1,200, 583.

Now if the highest of the four tones is raised 20*c.* to 603*c.*, and C remains, these two are as 12 : 17, and with their two resultant tones, A and the seventh harmonic of F, they form the accord 5 : 7 : 12 : 17, in cents 884, 267, 1,200, 603. This is the true form of the chord of the diminished seventh.

The difference of 20*c.* is one-fifth of an equal semitone.

The tenor part, moving from and back to C major on the notes 386, 316, 267, 204, 471, 386, divides the semitone $E\flat$–D in the enharmonic proportions proposed by Archytas, contemporary of Plato, as recorded and rejected by Ptolemy, namely:

$$\tfrac{36}{35} \times \tfrac{28}{27} = \tfrac{16}{15}, \text{ or } 49 + 63 = 112c.$$

The succession in the bass, meanwhile, is simply G, $A\flat$, A, G, G, C, that is, 702, 814, 884, 702 and 0 (1,200)*c*.

Distribution of Molybdenum

A VERY few elements constitute all save a minute fraction of the material of which plants and animals are made; but the small residuum contains a considerable, even a large, number of elements, stored up and accumulated by the organism and so present in larger amount than in the surrounding medium. We all know that iodine, for example, is abundant in seaweeds though the amount present in sea-water is very small indeed; and molybdenum is another element in much the same case. M. Eugène Cornec, several years ago, demonstrated the spectrum of molybdenum and of no less than seventeen other metals besides in the ash of seaweeds; and now I have succeeded in separating and estimating the molybdenum present in various plants and animals.

I happened to be analysing a certain coal-ash, and found traces in it of a metal the sulphide of which was soluble in sodium sulphide; by working on large quantities I was able to isolate enough of this metal for identification, and it proved to be molybdenum. One kilogram of coal was found to contain 0·21 mgm. of the metal, or 21 parts in a hundred million. I then began to look for molybdenum in all sorts of plants and vegetable products, and always found it, though the quantities were always small. The largest amount was found in beans and peas, namely, 3 to 9 mgm. per kilo; cereals come next in order, with 0·2 to 0·6 mgm.; while wood, leaves, and various fruits and vegetables contain only minute traces—cucumbers, for example, with 0·01 mgm. per kilo. Demarçay[1] had already demonstrated molybdenum in wood-ash, spectroscopically; my own method is a colorimetric one, based on the orange colour exhibited when a sulphomolybdate is heated in solution with ammonium chloride.

Ordinary plants must draw their supply of molybdenum from the earth, and accordingly I began to search for this element in various samples of soil; in a fertile soil I found from 0·1 to 0·3 mgm., on a moor I found 0·01, and on a barren sandy waste only 0·005 mgm. per kilo. I next analysed a number of mineral waters; but the only one (out of nineteen different samples) which contained an appreciable amount of molybdenum was the Source Perrière of La Bourboule, which contained 0·13 mgm. per litre. Mineral oils were found to contain molybdenum, sometimes in large quantity; the least amount was found in Persian crude oil, namely, 0·013 mgm., the largest in Mexican crude, which yielded no less than 5·55 mgm. per kilo. I then proceeded to look for molybdenum in the tissues of man and animals. The largest amounts I found in liver, and in the milt: for example, 1·5 mgm. per kilo, in the liver of ox or pig; while much smaller quantities, from 0·14 to 0·03 mgm. per kilo were to be found in blood, bile, milk, eggs and sundry tissues. Cod's liver contained 0·12 mgm. while haddock (whole fish) contained 0·03 mgm. per kilo; but in contrast to this I was unable even to detect molybdenum in a sample of forty litres of sea-water.

A relatively large quantity of molybdenum is contained in *Azolla*, a little aquatic plant which has become very abundant on the smaller canals in the neighbourhood of Delft. 264 gm. of the dried plant gave 0·298 mgm. of molybdenum, or 1·13 mgm. per kilo; and another sample, of 226 gm., gave 1·12 mgm. per kilo. On the other hand, the amount of molybdenum present in the canal water was very small indeed; it was necessary to operate on 23 litres before a titration could be made; and the amount obtained was only 0·021 mgm., or 0·0009 mgm. per litre. *Azolla* is remarkable for having a minute alga, *Anabæna Azollæ*, living in symbiosis in its tissues, and this alga is believed to be capable of fixing atmospheric nitrogen. Now H. Bortels[2] has made the interesting discovery that a certain microbe, *Azotobacter chroococcum*, which also possesses the power of fixing atmospheric nitrogen, is dependent for its healthy growth on the presence of molybdenum; and one begins to wonder what part the metal plays in *Azolla* and its symbiotic *Anabæna*. It has not been possible to separate these two symbiotic plants for purposes of analysis; and the amount of molybdenum which I have ascribed to *Azolla* is that of the two plants in their normal association.

General Transformation Theory in Hilbertian Space

ONE can write the Dirac's wave equation

$$\left\{\alpha_1 p_1 + \alpha_2 p_2 + \alpha_3 p_3 + \alpha_4 mc\right\} \psi = \lambda \psi \qquad (1)$$

in the matrix representation

$$\sum_{\sigma,\kappa} \left\{(\alpha_1)_{\tau\sigma}(p_1)_{\iota\kappa} + (\alpha_2)_{\tau\sigma}(p_2)_{\iota\kappa} + (\alpha_3)_{\tau\sigma}(p_3)_{\iota\kappa} + (\alpha_4)_{\tau\sigma} mc\right\} \psi_{\sigma\kappa} = \lambda \psi_{\tau\iota} \qquad (2)$$

which will be *invariant under any unitary transformation* of the Hilbertian spaces of spins and momenta ($(p_1)_{\iota\kappa}$ denote the components of the momentum matrix in the Hilbertian space).

Usually one considers only the Cartesian systems in Hilbertian space, but from a general point of view one is led to investigate the invariance of quantum laws under more general affine transformations. To assure this invariance one has to introduce the 'metric matrices' $\gamma^{\sigma\varrho}$ and $g^{\kappa\lambda}$ for the two Hilbertian spaces as new dynamical variables, and to write equation (2) as follows

$$\left\{(\alpha_1)_{\tau\sigma}\gamma^{\sigma\varrho}(p_1)_{\iota\kappa}g^{\kappa\lambda} + (\alpha_2)_{\tau\sigma}\gamma^{\sigma\varrho}(p_2)_{\iota\kappa}g^{\kappa\lambda} + (\alpha_3)_{\tau\sigma}\gamma^{\sigma\varrho}(p_3)_{\iota\kappa}g^{\kappa\lambda} + (\alpha_4)_{\tau\sigma}\gamma^{\sigma\varrho} mc\right\} \psi_{\varrho\lambda} = \lambda \psi_{\tau\iota} \qquad (3)$$

(where the covariant and the contravariant characters of the indices as usual are distinguished by their position).

To account for an external electromagnetic field, one usually introduces in the Dirac equation the potentials of the field, which causes a corresponding change in the eigenvalue spectrum of the equation. But if one starts from the general equation (3), one can always by an appropriate choice of the 'metric matrices' $\gamma^{\sigma\varrho}$ and $g^{\kappa\iota}$ ensure that this equation gets a given eigenvalue spectrum. This follows from the well known fact that by a simultaneous non-unitary transformation any two quadratic forms $H_{\iota\kappa}$ and $G_{\iota\kappa}$ may be transformed into diagonal forms, one of them becoming the unit form. We can thus formulate the principle of general transformation as follows:

It is impossible to distinguish between a set of states described by a Dirac equation for a free particle in a non-unitarian Hilbertian space and a corresponding set of states, described by the usual Dirac equation in a given external field.

Thus the electromagnetic field appears to be an expression of the non-unitary metric in the Hilbertian space in the same way that the gravitational field is an expression of the non-Euclidian metric of the space-time world.

Room Comfort

IN a note in NATURE of Nov. 12, p. 743, reference was made to the kata-thermometer as being considered too small for its purpose as an indicator of comfortable conditions in a room, and to the larger electrically controlled instrument, the eupatheoscope, described by Mr. A. F. Dufton, the surface of which is automatically kept at 75° C., a temperature corresponding to that of the clothed surface of the body in ordinary room conditions. This instrument was considered more suitable owing to its size.

The kata-thermometer does not indicate the rate of cooling of the body but of the bulb of the thermometer, which approximately is at the temperature of the skin of the face. The range of cooling powers which are best for comfort were fixed empirically in conditions which were admittedly fresh and pleasant. Like the skin of the face, the kata-thermometer is very sensitive to the cooling effect of wind.

I have shown that the infra-red rays from dull red and dark sources of heat produce uncomfortable sensations in many people. They tend reflexly to congest the nose and make it stuffy, the congestion lessening the nasal air-way. These effects are set aside by cool air, for example, by a fan blowing on the face. As the kata-thermometer is very sensitive to cool warming air, it is an excellent indicator of those conditions which give a fresh feeling. The mere securing of a certain cooling power and temperature of the clothed surface is not sufficient to give comfort, and as the small size of the kata-thermometer is actually an advantage, its utility is not surpassed by that of the eupatheoscope.

Colour-blind Motorists and Red Danger Signs

IT is not, I think, realised what a menace the colour-blind have become under present conditions; their contribution to the toll of the roads, for example, is never even mentioned. Most colour-blind persons are blissfully unaware of their abnormality and in Great Britain there are probably one hundred thousand colour-blind persons licensed to drive motor vehicles. Would-be drivers of railway trains are tested as a matter of course and some four per cent are rejected for defects in colour-vision, but no tests are imposed upon those who use the roads.

The peril of the roads is enhanced by our use of red as the sign of danger—the one colour which the ordinary colour-blind person cannot see at all—and it is instructive to don a pair of blue spectacles (copper glass) and to learn how the world appears to a daltonian. The danger is greatest, of course, at night, when the red rear-lights of vehicles, road obstruction lamps, reflectors on bicycles and *beacons* at cross-roads are well-nigh invisible and fail to convey any warning. Automatic light-signals which show red as a stop-sign may be a source of danger by day as well as by night.

As colour-blindness is largely congenital, it will doubtless soon be practicable to eliminate it. In the meantime all 'bus drivers should be tested (on November 5 one did not see my brilliant red rear-light and charged into the tail of my car), and coroners might well inquire into the colour-vision of those who at night drive down inoffensive cyclists.

Systems of Four Immiscible Liquid Layers

THE mixture described by E. Lester Smith[1] gives a system which separates into four layers, as stated, but does not appear to be stable. A specimen made up as described at first separated into four layers, but after long standing these become two layers. One sample of the system made up in January 1931 has now formed two layers, coloured brown, and separates into these two layers on standing after agitation. The phase rule deals with systems in true equilibrium.

Research Items

Ancient Civilisation in the Rift Valley.—Capt. G. E. H. Wilson discusses in *Man* for November the evidence for the existence of a forgotten civilisation in the Rift Valley, East Africa. The existence of ancient works, terracing, graded roads (the so-called elephant tracks) and irrigation works—canals and drainage—is now established not only in Tanganyika, but also in Abyssinia, Uganda, Kenya and Northern Rhodesia. The terraces, averaging in width at the top about one foot, but probably originally about three feet, follow the contours of the hills. The depth between terraces is about three feet. The roads, clearly not elephant tracks, point to a high state of civilisation. They are difficult to locate, though in places they are part of roads in use to-day. The points at present located suggest a system of communication running north and south on the eastern side of the Great Lakes, pointing to outlets by way of the Nile in the north and by Rhapta in the south, with possibly an intermediate route via Mombasa, the origin of which may prove very much more ancient than is thought. There are traces of an extensive system of irrigation at Uhehe, and in low-lying districts, such as the Mgeta River near Kisaki, there are river diversions which may be artificial. As to the authors of this civilisation, there are legends of an alien race dominating local peoples in both north and south Tanganyika. At present there is a great diversity of language and culture where those ancient works are found; but at some time the people may have been more homogeneous. If there has been an alien immigration, it is possible that it may have taken place so early as 1500 B.C., and that by the time of Solomon (970 B.C.) a flourishing trade already existed and the Sheban port of Rhapta had been established. It is suggested that this ancient civilisation may have originated in the north, spread through the Rift Valley over the highlands of the Great Lakes, and have reached Zimbabwe.

Sociological Value of Churches.—The problem of "The Churches and Social Well-being" is discussed by John Miner in *Human Biology*, September, 1932. An attempt is made to find some statistical evidence in the United States in support of the popular assumption that churches are not only the bulwarks of morality and social stability, but also promote social well-being in general. Correlations were calculated between the percentage of church members in each State and indices of wealth, education, health, and sexual morality. So far as his evidence goes, Miner finds no indication of any effective contribution of the churches to social well-being. States with large proportions of church members are on the average no healthier, no wealthier and no more literate than States in which the churches are weak, and show no lower illegitimate birth rates or death rates from venereal diseases. States with large proportions of Methodists and Baptists appear to be relatively poor and illiterate.

'Legislative Anthropology' in the United States.—Dr. Arthur Macdonald, who is well known for his advocacy of the study by anthropometric measurement of the members of legislatures as a body, as best representing the anthropological status of the population of their respective countries, has recently published in the *Congressional Record*, Washington, D.C. (Seventy-seventh Congress, First Session) an anthropological study of eighty-nine congressmen, representing various States, who may be taken as typical of the successful American in the prime of life. The great majority of them are of English or Scottish ancestry, while the remainder have a good sprinkling of English or Scottish blood. Their average age is fifty-three years. The average length of head is 196 mm., breadth, 156 mm. and height, 139 mm., cranial capacity, 1,625 c.c., and estimated weight of brain (Welcker's formula), 1,543 gm. Some interesting results emerge from a classification in State groups. The western south Central States (Arkansas, Louisiana, Oklahoma and Texas) give the greatest stature, 179 cm., greatest brain weight, 1,571 gm., and longest head, 198 cm.; the western north Central States coming next with brain weight 1,525 gm. and stature 177 cm. The lowest brain weight comes from the Pacific States (Washington, Oregon and California), of which the five members measured have a brain weight of 1,419 gm., head length, 191 mm. On the other hand, these five members have the greatest strength of hand-grasp—76 kgm.

Host-Parasite Relationship in *Olpidium*.—*Olpidium viciæ* and *O. trifolii*, which are found in the field only on *Vicia unijuga* and *Trifolium repens* respectively, are shown (S. Kusano, *J. Coll. Agric. Imp. Univ. Tokyo*, vol. 11, No. 4, 1932) by inoculation experiments to develop in sixty-three out of eighty-one species (sixteen out of twenty families) of phanerogams inoculated. The host plants react in two ways to the attack of the fungus. In one group the formation of a tumour results, while in the other no sign of infection is recognisable externally. The host of this second type may function as the fungus carrier, being susceptible to the parasite but immune from the disease. The hosts reacting in the first manner to *O. viciæ*, namely *Vicia unijuga*, *V. faba* and *Pisum sativum*, react to *O. trifolii* in the second manner; reciprocally the plant reacting in the first manner to *O. trifolii* exhibits the second type to *O. viciæ*. All parenchymatous tissues from the various plants liable to infection induce an apparent positive chemotaxis to the swarm cells of the fungus and the potassium ion is the active agent in this chemotaxis. Many susceptible plants remain unaffected in Nature because their anatomical characters, growth forms or habits prevent the parasite from approaching their susceptible cells. The morphological difference between the two forms of *Olpidium* is exceedingly slight and the range of their hosts exactly coincides. There is, however, a clear distinction between them as regards their effect upon certain plants.

Physiology of Ciliary Movement.—The first of a series of papers on this subject dealing with the effect of hydrogen ion concentration upon the ciliary movement of the gill of *Pecten* has recently been published by Dr. Shichiroku Nomura (*Sci. Rep. Tôhoku Imp. Univ.*, fourth ser., vol. 7, 1932). The most important conclusion reached, which appears to be based on sound experimental evidence, is that stoppage of the cilia in an enclosed chamber is not due to accumulation of carbon dioxide, as previously supposed, but to lack of oxygen. The supposed effect of carbon dioxide in regulating the rate of respiration in lamellibranchs by depressing ciliary activity is thus untenable, at any rate for the species examined.

Interesting figures are also given of the critical pH values for the stoppage of cilia by carbonic, acetic, phosphoric and hydrochloric acids, which range from 5·5 to 3·8 in the order given. The longer the period for which the gill was exposed to acid sea-water, the longer it took to recover. This result is not in agreement with Gray's work on *Mytilus* but this animal, unlike *Pecten*, is a member of the littoral fauna and is normally uncovered daily and the gills exposed to a low hydrogen ion concentration in the mantle cavity. After the gill cilia had been stopped by lack of oxygen, motility was recovered by re-admittance of oxygen even after the gill had been left overnight.

Determination of Sex.—Max Hartmann discusses some very interesting work on the determination of sex in *Die Naturwissenschaften* for July 29, 1932. In the higher animals and plants, the two kinds of sexual cells are readily distinguished, but passing to the simpler organisms, such as the Algæ and Fungi, forms exist in which the differences in form may be very slight and the two gametes are practically only distinguished by their behaviour—the type regarded as male, or so-called – (when no form difference is recognisable), usually being more active than the female or +. In the extreme case, even this physiological difference disappears. The school of workers under Hartmann at Berlin, working mainly on Algæ, have devised a good method by which they have shown that even in the extreme isogamous forms, a sharp distinction of the gametes into two kinds exists, which is expressed by the liberation into the culture solution of an actual sex-specific substance. If the filtrate from a + culture which contains bacteria, is added to a culture of the – type, a grouping of the gametes is induced, as when gametes of the + and – types are mixed, though actual fusion does not occur in the present case. The explanation given is that the bacteria in the one culture have absorbed a substance, which affects the behaviour of the gametes in the other culture in the same way as the presence of the actual gametes would have done. The gametes, though morphologically and physiologically similar, yet exude distinct substances according to whether they are + or – and only gametes of these opposite kinds will copulate.

Meteorological Observations in Southern India.—In a paper on the extreme dryness observed at Kodaikanal during the winter months, by S. L. Malurkar (*Scientific Notes, Ind. Meteorol. Dept.*, vol. 4, No. 43), an attempt is made to explain the occurrence at Kodaikanal of dry spells during which the relative humidity frequently falls below 10 per cent and attains at times values so low as probably to be far outside the range of accuracy of ordinary wet-bulb hygrometry. Kodaikanal is one of the hill-stations in southern India; it lies in lat. 10° 14′ N. and long. 77° 28′ E., at an elevation of 2,343 metres. Two common causes of exceptional dryness are the advection of air from high to low latitudes accompanied by a rise of temperature due to powerful solar radiation, and the gradual descent of air from high to low levels, such as takes place in many anticyclones, with consequent rise of temperature due to compression of the air as it comes under the higher pressure of the lower levels. In this paper the alternative explanations are critically examined in the case of Kodaikanal. An anticyclone is almost always to be found over southern India in winter, and incursions of dry cold air from northern India often take place round it, but on examining the observed humidities and temperatures over India at these times, no support is found for an explanation based on these. With the idea of descent of air from above, on the other hand, the observed course of events at Kodaikanal and other places fits well. There is often an inversion of temperature with a dry layer, and on plotting the relative humidity at Kodaikanal against the height of this layer as measured by registering balloons at Poona, it was found that the two were positively correlated; further, the occurrence of exceptional dryness was generally simultaneous at all stations with an elevation of 2,000 metres or more, and was apt to be absent from the stations at lower levels. These facts seem to leave little doubt that the exceptional state of the atmosphere is observed on those occasions when the inversion layer of the nearly permanent anticyclone is to be found at a lower level than usual.

Luminous Phenomena accompanying Earthquakes.—Shortly after the Idu earthquake of November 26, 1930, Mr. K. Musya collected many records of luminous phenomena observed at or about the time of the earthquake (NATURE, 128, 155; 1931). Since then, he has studied the phenomena attending four other earthquakes (*Earthq. Res. Inst. Bull.*, 10, 649–673; 1932). The most important of these is the South Hyuga earthquake, which occurred at 7.3 P.M. on November 2, 1931, the number of observations collected being 355. They were observed most frequently at the time of the earthquake and over a tract of country about 130 miles from north to south. The directions in which the lights appeared are varied, but most observers on the coast saw them towards the district in which the submarine epicentre lies. The luminescence usually seemed to radiate from the horizon or to be like a search-light turned to the sky, in colour most often blue or bluish. The phenomena were clearly not due to houses on fire, or to lightning or landslides, though some may be assigned to electric sparking or to meteors. But the author is convinced of the reality of the phenomena and of their connexion, in some way not at present understood, with the earthquake.

Charge of Thunder Clouds.—In the *Revue Scientifique* of September 10, C. Dauzère, director of the observatory at the Pic du Midi, discusses at some length the present position of our knowledge concerning the transfer of electricity from the clouds to the earth by rain drops and by lightning of the ordinary type. He gives summaries of the theories of Simpson and Wilson in regard to the polarity of thunder clouds, and of the two appears rather to favour Simpson's theory that the positive pole is in the lower parts of the front of the cloud and the negative pole in the rear and at the top of the cloud. According to a theory of his own, however, introduced in a number of papers published within the past five years, the ice particles of the cirrus clouds play a part in the distribution of electricity in the thunder cloud. This theory supposes that positive electrification of the ice particles caused by ultra-violet light leads to the condensation upon them of super-cooled water droplets carried upwards by the vertical currents in the cloud, and that the resulting hailstones have generally not had their positive charges neutralised by the time that they have become heavy enough to fall into the lower

forward parts of the cloud. M. Dauzère's view, therefore, is that the large positively charged drops normally found there, which are explained by Simpson as due to the mechanical break-up of drops exceeding a critical size, are partly derived from the cirrus level, and he regards the top of the cloud—or at least the overlying cirrus—as positively charged. But he considers all this part of the subject, and also the question as to whether positive or negative electricity is discharged by a lightning flash, as very speculative, that in fact there is only one point about which definite knowledge has been acquired since the time of Franklin, and that is in regard to the sign of the charge normally carried by raindrops; this charge has been found to be positive in widely separated parts of the world.

Nature of Martensite.—An interesting contribution to our knowledge of the nature of martensite is contained in a paper by Honda and Nishiyama (*Sci. Rep. Univ. Tôhoku*, series I, vol. 21, No. 3, 299). It has been known for some time that when a hardened steel is tempered, several physical properties show a sudden discontinuity at a temperature just above 100° C., as well as a more gradual change between 250° and 300° C. The meaning of the two sets of changes has hitherto been somewhat obscure, but it is now suggested that the first represents a transformation from the tetragonal form of martensite, which results directly from the quenching, to a cubic modification, whilst the latter is due to the breakdown of the cubic martensite to troostite. Since for both forms of martensite the size of the unit cube changes continuously with the carbon content of the steel, it is held that proof has been obtained that they are both solid solutions and not structures in which the carbide is present as particles of colloidal size out of solution. From measurements of the density it is shown in each case that the carbon atoms are arranged in the lattices interstitially and that the replacement theory is untenable.

Astronomical Topics

A Recent Sunspot and Magnetic Disturbance.—A large, single sunspot that was recently visible to the naked eye for a few days crossed the sun's disc between December 6 and 19. It was the return of the leader spot of a large group which had developed rapidly between November 16 and 21 and was then lost to observation around the sun's west limb. The position of the spot was, longitude 325°, latitude 10° north, and its area 600 millionths of the sun's hemisphere on December 7 and 450 millionths on December 14. The spot was most nearly in line with the earth on December 13·0, and on December 14 at 16^h a considerable magnetic disturbance began (in which the range in declination at Greenwich was nearly $\frac{1}{2}°$), thus strongly suggesting a connexion between the activity of this region of the sun and the earth's magnetism. Although the spot was observed with the spectrohelioscope at Greenwich, whenever the sky permitted, no activity in the nature of an eruption was seen in the light of Hα. The longest possible watch was limited, however, to two hours on December 12, so that combined observations from observatories abroad may be more decisive. It may be added that a sunspot of this size is rare but by no means unique during the epoch of minimum phase of the eleven-year cycle upon which the sun's activity has now entered.

New Comet, 1932*n*.—Mr. G. F. Dodwell, the Government Astronomer at Adelaide, has telegraphed to the Astronomer Royal announcing his discovery of a comet of magnitude 11. On December 17 at 1^h (probably local time, but telegraphed as U.T.), its R.A. was $23^h2^m23^s$, South Declination 28° 43′; the R.A. was increasing 3^m18^s daily, the declination diminishing 47′ daily, motion northward. Mr. Dodwell suggested identity with Tempel's comet, but this does not appear to be possible. The comet is on the meridian about 5 P.M.

The Leonid Meteors.—*Popular Astronomy* for December and Science Service, Washington, November 25, report that a fairly active shower was seen in the United States in the early hours of November 16.

At Dubuque, Iowa, the rate reached 240 per hour, and two bright meteors were seen after sunrise. At Yale Observatory it was noted that the proportion of bright meteors was large. Half of them were brighter than Procyon and one-fifth of them brighter than Sirius. At East Radford, Virginia, 734 were recorded in 3 hours; at Catskill Mountains, New York, 901 were recorded. The last two numbers, however, include many duplicates. At Harvard, Dr. P. H. Millman photographed the spectra of the trains of two bright meteors; the photographs had not been fully examined when the report went to press.

The above results suggest that the predicted time of maximum, Greenwich noon on November 16, was not greatly in error. Probably if the moon had been absent, this shower would have been considered a fairly good one.

Mass of the Galactic System.—Dr. J. H. Oort has investigated (*Bull. Astron. Instit. Netherlands*, vol. 6, No. 238) the force exerted by the galactic system in a direction perpendicular to its plane. His methods involve so many steps that they cannot be summarised within the limits of a note, which is therefore limited to his conclusions. The acceleration perpendicular to the plane increases proportionally to the distance from the plane up to a distance of 200 parsecs, and then remains nearly constant to a distance of 500 parsecs. The mass per cubic parsec in the sun's neighbourhood is 0·092 sun, but in the larger region including stars to 13·5 visual absolute magnitude it is only 0·038 sun; this would, however, be increased if still fainter stars were included. The mass of interstellar dust and gas is concluded to be only a small fraction of that of the stars. The mass per cubic parsec is shown to be of the same order as that deduced by Dr. Hubble for the Andromeda nebula. The nebula N.G.C. 4594 indicated greater mass in proportion to its light; but the light of this nebula is dimmed by a belt of absorbing matter.

A note at the end of the article gives reasons for believing that van Maanen's star has a mass 3 times the sun's, with a radius of 5,000 km.; the resulting Einstein shift to the red is 240 km./sec.; it is pointed out that it will be possible to distinguish this from true recession by measuring the change of proper motion in forty or fifty years.

Durban Meeting of the South African Association for the Advancement of Science

THE thirtieth annual meeting of the South African Association for the Advancement of Science was held in Durban on July 4–9, under the presidency of Prof. P. J. du Toit. The meeting was very well attended and 117 papers were read. The South African medal and grant were presented to Prof. J. W. Bews and the first British Association medal to Dr. Nellie F. Paterson at the close of the presidential address. Popular evening lectures were given by General J. C. Smuts on "Climate and Man in South Africa" and by Prof. B. de St. J. van der Riet on "Essential Oils". There was a reception by the mayor and councillors and numerous excursions to places of scientific interest in the neighbourhood. [The papers presented at the meeting are now available as vol. 29 of the *South African Journal of Science* (Johannesburg: South African Association for the Advancement of Science, 1932. 30*s*. net).]

The presidential address on "Africa's Debt to Science" was delivered by Prof. P. J. du Toit. To illustrate what science has done for Africa, advances in preventive medicine and in veterinary science were considered in detail. Progress in the science of nutrition, including the rôle of vitamins and minerals for man and stock, was summarised and the interrelation of botanical and veterinary science indicated. Improvements in refrigeration and in communication were noted. What science can do for Africa in the future was indicated as increase in health, reduction of infantile mortality, eradication of diseases such as malaria and East Coast fever, organisation of native races and the development of large white dominions in Africa. According to Prof. du Toit, Africa should do much more to further research. The best use is not being made of either the money or the men available. Economy in brain power is necessary and men of great research capacity should not be wasted doing the work of junior clerks. Research should not be sacrificed for economy. Organisation of research is necessary and also the creation of conditions such that outstanding men can devote themselves to research.

Prof. R. W. Varder gave an account of recent work on "Particles and Waves" as his presidential address to Section A. The quantum theory in relation to light and waves was discussed and the photoelectric and Compton effects were contrasted with de Broglie's views. The interference experiments of Thomson and their mathematical solutions, leading to the uncertainty principle of Heisenberg, were discussed. Quantum mechanics, radioactive decay and the structure of the atom in relation to modern spectral theory were also considered.

The presidential address to Section B, delivered by Dr. L. J. Krige, dealt with "The Geological History of Durban". After the deposition of the oldest existing South African rocks, included in the Swaziland and Pongola systems, intrusions of granite occurred. The earlier formations were afterwards denuded, and granite is the most ancient rock near Durban. Succeeding formations are not represented in Natal. Each of the old systems has a bed of tillite, indicative of arctic conditions, and the Dwyka ice age was the severest known. At the break-up of Gondwanaland the Cretaceous beds of Durban Bay were deposited. In the Pleistocene the Bluff Peninsula was built up and the sea level oscillated to 500 ft. In post-Pleistocene times, sea level did not rise so high as in previous inter-glacials, but at its greatest height a spit was built from the Bluff to the mouth of the Umgeni River, which opened into the original Durban Bay. Its silting up formed the Durban flat and resulted in its present course to the sea. Sea level subsidence left the old alluvial flats above sea level and several rivers formed new flats. Remains of marine wave-cut terraces occur between the Bluff and the Umbogintwini River and mark its former position.

Prof. E. M. Robinson considered "The Development of Veterinary Bacteriology in South Africa" in his presidential address to Section C. The early work on bacteriology here was noted, then special diseases were considered. The work on anthrax, including immunisation, attenuation and methods of administration were described. The gas gangrene group includes the organisms of blackquarter and the various methods of treatment were described. The usefulness of formolised vaccines against *B. welchii* and *B. œdematiens* was noted. The work on contagious abortion due to *B. abortus* and *Vibrio fœtus*, and the salmonelloses, of importance to the poultry industry, were discussed. Bovine tuberculosis is receiving attention; avian tuberculosis does not seem widespread. *C. parabotulinum bovis*, responsible for lamsiekte of cattle, was discussed and miscellaneous bacteriological conditions in domestic animals noted.

Dr. R. Broom spoke on "Evolution as the Palæontologist Sees It" in his presidential address to Section D. The hypotheses of Darwin and Lamarck were considered palæontologically. Evolution, said Dr. Broom, is not by large mutations but by almost imperceptibly slight modifications along definite lines, from small generalised forms to large highly specialised types, as is shown by a wealth of examples. The evolution of horns in fossil and modern forms was considered. Many structures that were useless developed in the past, and their owners were failures. Evolution is continuous, not backwards and forwards. About 99 per cent of all known fossil forms became specialised in some direction so that they could not adapt themselves and so perished. The Therocephalia remained small and generalised. By the middle of the Eocene all known mammalian orders were established, all small generalised types had specialised and hence no new orders of mammals could afterwards appear. The belief was expressed that a psychic and a cosmic force had been at work and that some force had restrained the specialisation of the primates, evolving a higher type of brain, and causing man to appear. As evolution has practically finished and cannot be repeated unless all higher life is wiped off the earth and a new start made, man may be the end to which some power has guided evolution.

The presidential address to Section E, by Miss D. F. Bleek, was entitled "A Survey of our Present Knowledge of Rockpaintings in South Africa". Four areas in southern Africa were delimited. The first comprises the western Cape Province, Cape Midlands and southern part of the eastern Cape Province. There are three subdivisions: the western, with pictures showing poor work, little grouping, few superpositions; the midland, with many group scenes, more superpositions and bichromes in the

latest layer; the south-eastern, less developed and mostly monochromes. The second area comprises the north-east Cape Province and foothills of the Drakensberg in Basutoland, the Free State and Natal. Caves are crowded with pictures, there are numerous superpositions, group scenes are frequent and monochromes, bichromes and polychromes are numerous. Towards the north, rock engravings replace paintings, the best being in the Transvaal. The third area, between the Kalahari and the Atlantic, has polychromes and dressed human figures of a curious type not found in areas 1 and 2. The fourth area, Southern Rhodesia, has granite as rock background, monochrome animals standing quietly, trees and plants and two types of human bodies; the workers seem to have been some branch of Bushmen. Southward migrations of different branches of the race seem to have occurred, one degenerating in art as it went, the other developing a high state of perfection.

The Rev. Prof. J. du Plessis dealt with "Missions as a Sociological Factor" in his presidential address to Section F. The influence of early missions, before the colonial era began in 1884, on the black races of Africa was considered. Before 1884, the influence of missions on the general social life of the African was in part destructive; witchcraft, poison ordeal, human sacrifice, etc., being banned. Hygiene, sanitation, clothing and housing, industry and agriculture were introduced. The educational methods of early days were open to criticism, since the English public school system was imposed on people to whom it was not applicable. Adoption of European methods of life and the social status given them by the missionaries alienated them from their people. The introduction of better food products and teaching of trades in the early days were commended. The missionary carried the gospel, but in his wake came the traders and the Government. These contacts meant change of the old social order, and the value of missions was that they enabled the native to make the transition from old to new without moral and social disaster. New culture must be grafted on the old stock of native life. Missions are still necessary as a permanent and not merely permissive factor in the evolution and uplift of the native races.

In Section A a paper was given on the determinantal properties of oblong matrices; astronomical papers dealt with the pulsation theory of Cepheid variation, Tempel's comet 1866 (1) of the Leonid meteors, and the parallax of Nova Persei, 1901. The definitions of mechanical quantities were discussed. A new type of continuously variable inductance of fixed resistance was described. A series of papers dealt with the Electricity Supply Commission, the cost of generating and distributing electricity and electrostatic capacity. Recent investigations on cosmic rays and on Wilson chamber experiments on δ-rays were described, and a note on polarised light-stress apparatus was presented. Mechanical strength of aggregates, soil erosion and its prevention, and veld reclamation were subjects of discussion.

In Section B there were several joint meetings with other sections. Papers of geological interest dealt with the problem of past climates and peculiar little rock basins at Isipingo, Natal. The essential oils of *Empleurum serratulum* and of certain veld bushes in the Cape Western Province were described, as was the chemistry of the roots of *Arctopus echinatus*, and a further contribution to knowledge of the medicinal springs of South Africa was made.

In Section C a number of papers of mycological interest dealt with *Helminthosporium* parasites of cereals and wild grasses, the genus *Hemileia*, of importance to coffee growers, aster wilt, South African Clavariæ, various new South African fungi, die-back in *Pinus insignis* and a fungal infection on a tsetse fly. Bacteriological papers were concerned with the Weil-Felix reaction in heartwater, the serological diagnosis of horse sickness and the distribution of *Azotobacter* in Transvaal soils. An ecological study of the wattle bagworm, involving the possibility of controlling the insect by salting the soil, was presented, while another paper dealt with the physico-chemical changes produced in soils by the addition of salt. A series of papers of much interest to agriculturists related to work on intensive grazing on veld, experiments with improved pastures in the coastal belt, the relation of fertiliser treatment to soil reaction under turf, a pasture study of grazing conditions on a Potgietersrust farm, and a regrouping of cultivated barleys, with suggestions on the classification of cultivated plants. A revision of the genus *Lopholæna* was given. Other papers dealt with the cytology of the pollen mother-cells of certain plants, the aims and requirements of the International Committee on plant sociology and phytopathological notes.

In Section D papers of much entomological interest dealt with the embryological development of *Euryope terminalis*, the early stages of some South African hesperids, the biocœnosis of the plant *Gnidia laxa*, the possibilities of combating wattle bagworm with insecticidal dusts, and the control of *Glossina pallidipes*. Embryological papers dealt with developmental stages in the skulls of geckos and the morphology of the skull of *Hyperolius*. Papers on the morphology and phylogenesis of the Pareiasauridæ were of interest to palæontologists. Protozoological papers dealt with new parasitic Protozoa, including new species of *Isospora* and *Eimeria* from snakes and fish, with the freshwater Rhizopoda from the Worcester District of the Cape, with new species of *Nebela* found in South Africa and with the rate of growth of gregarines. *Testudo verreauxi* was discussed as a study in variation. The ultra-violet content of South African sunlight and the effect of underground work on the erythrocyte count of miners were considered. The validity of the Polypedatidæ as an autonomous family of the Anura was considered from the detailed anatomy of a number of genera. The significance of seasonal egg production in predicting the yearly total was of much interest to farmers. Baboon crania from Cathkin Peak district were described. South African Ancylidæ and the occurrence of schistosomiasis at river mouths were discussed. Two papers of much interest and causing much discussion were given in joint meetings with other sections and dealt with biology in relation to modern civilisation and with glands in relation to personality.

Section E had papers mainly centring round prehistory and social anthropology. The prehistory of South Africa and western Europe, the Smithfield and Wilton industries, and the archæology of the Cathkin Peak district were discussed. Rock shelters and archæological sites at Isipofu near Durban and at Salisbury Commonage were described, and papers were given on prehistoric South African defences and the ancient forts at Penhalonga, Southern Rhodesia. Strandlooper middens and implements in Natal were described, the occurrence of true burins in the Cape Province was notified, and an account given of the South African cleaver or biseau. The origin and

phallic character of conical and perforated stones were discussed. Some South African Bushman paintings and rock engravings were described, and the weathering of granite in relation to such paintings was considered. The Bantu potting industry and its impact on other native potting industries in South Africa were described. Of much interest were papers dealing with the history and distribution of the bow and arrow in South Africa, the name 'Hottentot' in the records of early travellers, and the drums of the Zulu. An extraordinary Nyasaland dance mask was described. Skeletal remains from a gold prospecting trench in the Matopos were, on the whole, considered to be of Bushman origin. The results of culture contacts on the Xosa and Pondo families were reviewed.

In Section F, economists discussed the relations of currency and capital, the economics of the hire-purchase system and the scope and method of business economics. Historical papers dealt with the influence of the tsetse fly on South African history, early South African rock inscriptions, early road administration in the Cape and mining in South Africa, and a defence of Sir Benjamin D'Urban was presented. Educationists discussed the present system of vocational training, an experimental scale for measuring the attitude of the white to the native, Freudian classification of the instincts and its application to some problems of civilisation. Basic English was recommended as a foundation for bilingualism. An interesting analysis of what becomes of boys after they have left school was given. A paper of outstanding social importance dealt with education and economic condition in relation to size of family, the results embodying analysis of such in connexion with nearly 50,000 families.

The next annual meeting of the Association will be held at Barberton, under the presidency of Dr. H. Spencer Jones, in July, 1933.

H. B. FANTHAM.

The 'Butterfly' Map Projection

IN NATURE of October 22 an account was given of the "'Butterfly' Map Projection" devised by Mr. B. J. S. Cahill, of Oakland, California. To save space and to use *one* instead of *three* world maps, Mr. Cahill combined his three variants in one drawing which he referred to as a *diagram*. We regret, however, that the writer of the article in NATURE misconceived the diagram, so that his comments upon it misrepresent the character and value of the projection. In justice to Mr. Cahill we print below a condensed statement sent by him referring to the completion of the theory, tabulated computations and diagrams of his decentralised octahedral system of projection begun thirty years ago.

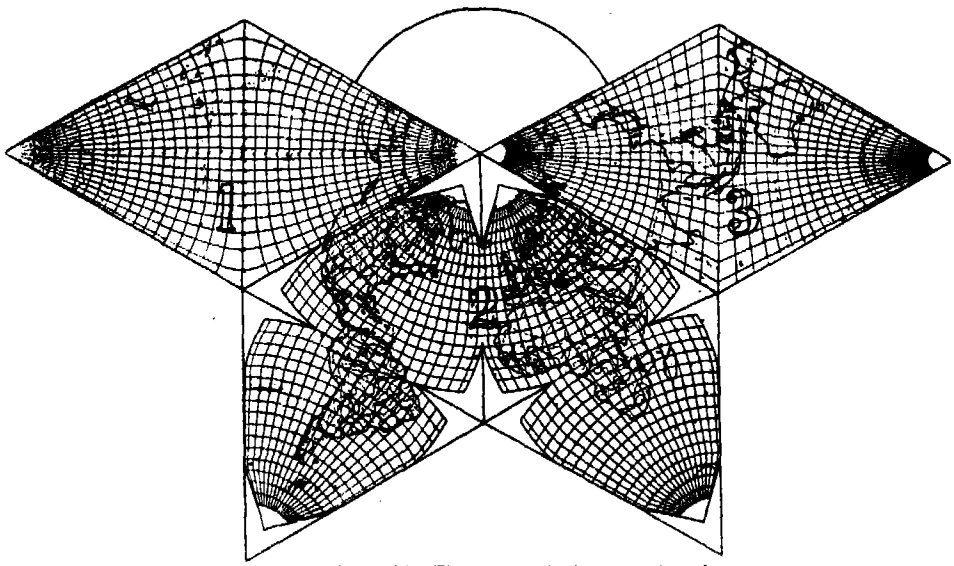

FIG. 1. Butterfly map of the world. The three variants are condensed to one diagram.

Earlier accounts published in Edinburgh 1909, Boston 1912, Gotha 1914, etc., describe a single 'maid-of-all-work' map now superseded by The Three Variants here condensed to one diagram (Fig. 1) and severally defined as to scientific quality and specific application as follows:

(1) The Orthogonal, Conformal or Orthomorphic Variant, a three-way continuum, rhombic type, for use mainly as an international meteorological base map from which local synoptic charts are cut, to be reassembled after isometrical data is added to form *daily single weather maps in the interest of* long range forecasting.

(2) The Authalic, Equivalent or Orthometric Variant, a land map for anthropogeographical, statistical, economic, educational and general geosophical purposes.

(3) The Gnomonic, Central or Orthodromic Variant, with double tetrahedral extensions, for geodesic, navigational and geophysical problems of sea, land, air or 'ether'. The practically undistorted eight charts of this variant are to have full topographical details. Alternate sets of four of these charts are also enlarged by encroaching on one-third of the adjacent ones to cover the facets of right and left enveloping tetrahedrons, thus yielding two sets of reciprocally overlapping expansions of

the original octants, since any octahedron can, by adding small tetrahedrons to alternate faces, be extended to positive and negative large tetrahedrons. By means of this fortunate geometrical fact the orthodromic service of this double set of tangent planes exceeds by far the service of any single plane possible.

Supplementing this variant are simple graphic diagrams for (*a*) continuing any line from chart to chart around the world, (*b*) joining any two points anywhere in one great circle, (*c*) measuring with precision all distances whether across any one, four or six charts, (*d*) converting all forward and retro-azimuths to true compass directions or vice versa to or from any point on the entire globe.

The 'Butterfly Map' is deliberately designed and mathematically detailed to meet the needs of ever growing world-wide problems and to help mankind above all things "to learn to think planetarily".

Atmospheric Tides

IN a paper entitled "Tides in the Atmosphere", in *Scientific Monthly* for August, J. Bartels gives a simple summary of our present knowledge concerning phenomena that would interest many people but for the intricate mathematics involved. He states that these tides have been studied lately by magneticians rather than by meteorologists because they assist the interpretation of terrestrial magnetic data. The main facts deserve, however, to be noted by meteorologists and others for whom this summary should, therefore, be of value.

It appears that our understanding of atmospheric tides still rests mainly on the resonance theory of Kelvin, developed later by Rayleigh and Margules. Analysis of long series of barograms has brought to light several small periodic variations of atmospheric pressure due to the tidal action, either thermal or gravitational, of the sun and the moon, and tidal theory is largely successful in accounting for them. The relative simplicity of atmospheric as opposed to oceanic tides, it may be noted, is due to the fact that the resonance properties of the atmosphere as a whole enhance the world-wide oscillations and repress local irregularities. Of the solar tides there are the travelling 12 hour wave with maxima at 10 a.m. and 10 p.m. local mean time, the 12 hour wave between polar and equatorial regions, with fixed nodes in about latitudes 35° N. and S., the 8 hour travelling wave, which shows a reversal of phase between summer and winter, and the 24 hour travelling wave. The two 12 hour waves and the 8 hour wave are appreciable mainly because the resonance factor for them is large. In the case of the 24 hour wave on the other hand, because of the very small resonance factor, the amplitude is very small in spite of the magnitude of the 24 hour temperature wave that causes it. The demonstration of the existence of the small lunar 12·4 hour and of the much smaller 24·8 hour wave is a recent success, Airy having failed to find even the 12·4 hour wave from an analysis of no fewer than 160,000 hourly observations at Greenwich. These lunar waves are simple gravitational waves owing little to resonance.

An interesting point is that the favourable resonance properties of the atmosphere for the 12 hour and 8 hour waves is apparently fortuitous. If the earth were to lose about thirty per cent of its atmosphere, none of the world-wide oscillations of pressure would be observed.

University and Educational Intelligence

BIRMINGHAM.—At a degree congregation held on December 16, the degree of D.Sc. was conferred on William Leach for numerous published papers on plant ecology and on plant physiology, especially on respiration.

Fourteen candidates also received the degree of Ph.D., namely: two each in physics, civil engineering, mining, metallurgy, and zoology, and one each in botany, chemistry, electrical engineering, and mechanical engineering.

CAMBRIDGE.—Dr. T. C. Phemister, of St. John's College, has been appointed University demonstrator in mineralogy and petrology in succession to Dr. A. G. Hutchinson, who has resigned.

Mr. C. F. A. Pantin, of Trinity College, has been nominated to use the University's table at the Zoological Station at Naples.

Dr. R. McG. Carslaw, of St. John's College, has been appointed advisory economist and head of the Farm Economics Branch.

It has been decided that in the regulations for the John Humphrey Plummer professor of inorganic chemistry, the word 'inorganic' should be replaced by 'theoretical'.

EDINBURGH.—The University Court has received with great regret intimation from Sir Edward Sharpey Schafer of his intention to retire from the chair of physiology at the end of the current academical year. He was appointed to the chair in 1899.

On the recommendation of the Senatus, Dr. J. B. Todd, lecturer in engineering, has been appointed a reader.

LONDON.—Major-General Sir Frederick Maurice, professor of military studies and member of the senate of the University of London, has been appointed principal of East London College as from the commencement of next session in succession to Mr. J. L. S. Hatton.

PROF. H. B. FANTHAM, professor of zoology in the University of the Witwatersrand, has been appointed Strathcona professor of zoology in McGill University, Montreal, in succession to Prof. A. Willey, and is taking up his new appointment immediately.

THE Cecil Peace Prize for 1932 has been awarded to Mr. A. J. Mackenzie, of the University of Edinburgh, for an essay on "The Danger from the Air. Discuss Possible Methods, by International Convention or otherwise, of dealing with it". This prize of £100 is offered yearly for an essay on a subject bearing on the principles or work of the League of Nations and is open to students less than twenty-five years of age of any university or university college in Great Britain or Northern Ireland.

THE annual meeting of the Mathematical Association will be held at the Institute of Education, Southampton Row, London, W.C.1, on January 5–6, under the presidency of Prof. G. N. Watson. Several papers will be read and a discussion on "The Study of Statistics in a School Course" will be opened by Mr. F. Sandon. The presidential address, to be delivered on January 5 at 3.45, will be entitled "The Marquis and the Land Agent: a Tale of the Eighteenth Century". Further particulars can be obtained from the Hon. Secretary, Mr. C. Pendlebury, 39 Burlington Road, Chiswick, W.4.

Calendar of Geographical Exploration

Dec. 25, 1539.—Discovery of the Amazon

Gonzalo Pizarro, brother of the conqueror of Peru, set out from Quito to find if there was truth in the rumour that beyond Quito was a land where cinnamon grew. His party crossed the snowy Cordilleras and in the valley of the Napo experienced two months of steady rain. Forest impeded their progress, so Pizarro built a ship in which Orellana was sent ahead to find food to bring back to the starving party. Orellana found none and instead of returning sailed down the Amazon to the sea. Pizarro, with the remnant of his party, returned to Quito in June, 1542. The discovery of the Amazon was dearly bought, for of Pizarro's party, 4000 Indians and 210 Spaniards perished.

Dec. 27, 1831.—Voyage of the *Beagle*

H.M.S. *Beagle* sailed from Devonport under Capt. FitzRoy to carry out surveys in South America and some islands of the Pacific and also to make chronometrical observations. The voyage became memorable because Charles Darwin was invited to accompany the expedition, which lasted nearly five years. He afterwards published his famous journal, and undoubtedly much of his subsequent work was inspired by this journey and especially by what he saw in the Galapagos Islands. (See NATURE, 128, 1065, Dec. 26, 1931.) The *Beagle* supplemented the surveys begun by King and FitzRoy in 1826–30 on the coasts between the Plate River and Chiloé; it completed the coast survey as far as Guayaquil. The Santa Cruz River was followed inland for about 250 miles to within sight of the Andes. In addition, FitzRoy visited the Paumotu Archipelago, the Society Islands, New Zealand, Australia and the Keeling Islands, in the course of his circumnavigation of the globe.

Societies and Academies

LONDON

Society of Public Analysts, Dec. 7.—J. Cecil Maby: Further notes on the identification of woods and charcoals. The characteristic structures of the charcoals of hazel, horsechestnut, hawthorn and apple were described and the difference between the 'sycomore' wood of the ancient Egyptians and English sycamore was demonstrated.—Winifred E. Smith and Edith K. Waller: The characteristics of millet oil. Whole millet seed yielded 3·9–4·7 per cent of a semi-drying oil consisting mainly of glycerides of linolic and oleic acids, and having a high acid value. It contained nearly 5 per cent of unsaponifiable matter, from which was separated a crystalline compound, melting at 285° C. and having an elementary composition differing from the 'panicol' described in 1888 by Kassner.—H. N. Griffiths, T. P. Hilditch and J. Rae: The stability of vitamin A in cod liver oil emulsions. The vitamin A potency of cod liver oil emulsions as measured by the antimony trichloride test and spectrographic examination, showed no appreciable decrease (as compared with the original oil) for at least four months. At six months there was evidence of some change, but chiefly in the original oil. If kept in well-stoppered amber glass bottles in the dark, cod liver oil emulsions could probably be kept without appreciable alteration for seven or eight months. Development of acidity in emulsified oils is attributed to the presence in minute quantity of a lipoclastic anærobic organism.—E. Lester Smith: The validity of the Lovibond tintometer method in the assay of vitamin A. A suitable technique for making accurate measurements of the blue coloration in the antimony trichloride test by means of the Lovibond tintometer was described; the results thus obtained agree closely with the vitamin A potency of an oil, as measured by the spectrographic method.—A. I. Bacharach, E. Lester Smith and S. G. Stevenson: Some physical and chemical properties of ergosterol and calciferol. An outline was given of the probable constitution of ergosterol and its derivative calciferol, and the melting points, optical rotation and other physical and chemical properties of the two compounds were tabulated.

EDINBURGH

Royal Society, Dec. 5.—A. G. Hutchison: The metamorphism of the Deeside Limestone, Aberdeenshire. This limestone, which Prof. Read has correlated with the Loch Tay limestone of the Central Highland Dalradian succession, is in the sillimanite grade of regional metamorphism. The occurrence of plagioclase felspars more basic than oligoclase distinguishes it from the Loch Tay diopside limestones of the almandine zone. Contact metamorphism by newer granites produces hornfelses referable to Goldschmidt's classes 7–10, and unstable types. Subsequent pneumatolytic and hydrothermal action accounts for pegmatites and limestone with scapolite, prehnite, zeolites, etc. The order of formation of minerals in the hydrothermal phase with falling temperature is grossular (doubly-refracting), zoisite-epidote, albite, prehnite, analcite, thomsonite and apophyllite. Successive alterations of the interbedded greenstone series are also considered.—Mary G. Calder: Notes on the Kidston collection of fossil plant slides, (1.) The anatomy of the axis of *Lepidodendron Brownii* Unger sp., with special reference to the relationship between this stem and *Lepidostrobus Brownii* Unger sp. A previous description by Prof. Chodat in 1911, having been made from a single transverse section, does not mention certain important features of the pith, xylem, phloem, outer cortex and leaf-traces. The comparison with *Lepidostrobus Brownii* has been revised and more fully discussed, particularly with reference to the cone pedicels, not known to Prof. Chodat, which were described by Zeiller in 1911. Prof. Chodat's identification of the stem as the vegetative axis which bore the cones known as *Lepidostrobus Brownii* receives further confirmation.—W. J. Hamilton: Restoration and regeneration of the epithelium and endometrium of the uterus of *Cavia* after parturition in non-pregnant animals. This process has not hitherto been described in detail in the guinea pig. After parturition the uterus is completely lined by columnar epithelium except where the placental pedicle was attached. This site becomes a cleft filled with organised blood-clot over which new epithelium grows. The old epithelium is shed from the rest of the uterus and new epithelium formed from gland mouths, consisting first of flattened cells which become cuboidal and ultimately columnar. Below the union of the uterine horns restoration is by the superficial endometrial mesodermic cells becoming epithelial. *Pari passu* the endometrium is restored from a fibrous to a cellular structure.—H. Briggs and R. P. Sinha: Expansion and contraction of coal caused respectively by the sorption and discharge of gas. Small but definite linear expansions in eight varieties of coal, in consequence of their

contact with methane or carbon dioxide under pressure, were measured by the authors and shown graphically. Pressures ranged from zero to 300 lb. per sq. in. The coal specimens were prepared in prisms about 75 mm. long, and the specimens included two of anthracite, two of durain, three of clarain (mixed durain and vitrain) and one of impure cannel. The physical reaction in most cases took a long time to reach completion; though small, it is definite and apparently reversible. The effect of adsorbed moisture was briefly discussed. The corresponding changes due to dry coal adsorbing moisture had yet to be investigated.—W. O. Kermack, W. H. McCrea, and E. T. Whittaker: On properties of null geodesics, and their application to the theory of radiation. The conception of a transport vector along a null geodesic is employed first to derive a new general definition of spatial distance, and secondly to derive a new invariant depending on two neighbouring null geodesics. The latter is used to obtain a general formula for the Doppler effect in general relativity. The same result holds for propagation by waves and by light quanta. The Doppler effect vanishes for two systems at relative rest, with a very general definition of relative rest. Some special cases are worked out in detail.—L. T. Hogben: A matrix notation for Mendelian populations. By the use of a matrix notation the unwieldiness of expressions encountered in the theory of consanguineous unions, systems of inbreeding and correlation of relatives when transmission is sex-linked can be avoided. The appropriate operations are defined and illustrated by application to known theorems of inbreeding and a series of new theorems concerning consanguineous matings are given.—A. C. Aitken: Graduation of data by the orthogonal polynomials of least squares. In the fitting of polynomial curves to equidistant data the use of the orthogonal polynomials of Tchebychef is known to possess great advantages. The author develops the properties of these polynomials, gives new forms for them, and introduces new arithmetical methods depending on repeated central summation.

CRACOW

Polish Academy of Science and Letters, Oct. 10.—**W. Swietoslawski**: A universal boiling point apparatus and its application. By means of this apparatus the following three temperatures may be determined: the boiling point of the liquid (solution), the condensation temperature of the first bulb of the fractionating column, and that of the condensation after the vapours have been fractionated.—**W. Swietoslawski, Mlles. A. Dorabialska and E. Turska**: The spontaneous emission of neutrons by certain non-radioactive elements. The analysis of the table of the known elements shews that the α-, β- and H-transformations cannot explain the production of the existing isotopes, without admitting the possibility of the emission of neutrons. Attempts at proving the decomposition of elements with production of neutrons have resulted in the proof of neutron emission in the cases of sodium fluoride and metallic arsenic.—**J. Biborski**: The histological structure of the veins of the frog, *Rana esculenta*.—**S. Sekutowicz**: Studies on the development and the biology of *Caryophyllaeus laticeps*.—**Z. Raabe**: Researches on certain species of the genus *Conchophthirus* Stein.—**J. Jakobiec and T. Marchlewski**: The influence of repeated connexion between closely related animals on the biological characters and the commercial value of the domestic pig.

SYDNEY

Linnean Society of New South Wales, Sept. 28.—**J. McLuckie and A. Burgess**: Mycotrophism in the Rutaceae. (1) The mycorrhiza of *Eriostemon Crowei* F.v.M. Two fungi are recorded as occurring in the young roots. One is a phycomycetous form giving rise to arbuscules and vesicles, the other, a moniloid type resembling *Rhizoctonia*. This affords confirmation of Peyronel's double infection theory. From a physiological point of view the former is more important. Large quantities of fatty substances accumulate in its hyphae and are afterwards transferred to the host, thus augmenting its carbonaceous supplies. In addition 'vesicles' are formed. These contain numerous nuclei and are packed with fat. Later the contents are withdrawn and the structures collapse. It is suggested that these are reproductive bodies the functions of which have been interrupted.—**G. H. Hardy**: Two new Australian species of *Pollenia*. One Victorian and one Queensland species of the genus are described and their genitalia figured.—**G. H. Cunningham**: The Gasteromycetes of Australasia. (15) The genera *Mesophellia* and *Castoreum*. Both genera are members of the Lycoperdaceae, though differing sufficiently from other genera placed therein to warrant the erection of a third tribe to contain them. *Mesophellia* contains two or possibly three species, namely *M. arenaria*, *M. pachythrix* and *M. castanea*, which are confined to Australia and Tasmania. *Castoreum* likewise contains three species, *C. radicatum*, *C. avellaneum* and *C. cretaceum*, also endemic to Australia and Tasmania.

Royal Society of New South Wales, Oct. 5.—**F. W. Booker**: Note on the internal structure of *Barrandella* and *Sieberella*. The descriptions of *Barrandella linguifer*, Sowerby, and *Sieberella galeata*, Dalman are amended and a comparison with *Barrandina Wilkinson* and *B. minor*, is made.

Forthcoming Events

TUESDAY, DEC. 27

ROYAL INSTITUTION, at 3.—(Christmas Lectures). Prof. A. O. Rankine: "The Round of the Waters" (succeeding lectures on Dec. 29, 31 and Jan. 3, 5 and 7).

Science and Empire Building

IT is distinctly unusual for the Governor-General of a great Dominion to deliver an important scientific address; yet that is what recently happened in New Zealand when Lord Bledisloe gave the Cawthron lecture, which is there regarded as the annual pronouncement *par excellence* on modern movements in science and their relation to the life of the community. Lord Bledisloe chose as his title "A Conspectus of Recent Agricultural Research" and the choice was doubly happy in that the subject is of profound importance to the people of New Zealand and that he himself is so well qualified to deal with it. Nowhere in the world is scientific agriculture more highly developed and nowhere can one gather a more discriminating and better informed audience to listen to an agricultural lecture than at the Cawthron Institute on the occasion of this annual function.

The cordial welcome given to the discourse by the New Zealand Press was much more than a compliment to the popularity of the Governor General. The address is admirable both in range of subject matter and in presentation.* Lord Bledisloe begins appropriately with an account of the work on soils and plant growth, this being fundamental to all agricultural systems. The account of the Rothamsted experiments on cultivation and fertilisation of crops and on the making of new pastures is followed by a description of the Jealotts Hill investigations on the intensive manuring of pastures, and of the Aberystwyth work on the improvement of hill grazing. This naturally leads to a survey of the effects of mineral deficiencies on the composition of the herbage and on the health of the animals grazing thereon. Fundamental studies on this subject are made at the Rowett Research Institute at Aberdeen, but New Zealand has contributed in no small measure to the advances made in recent years.

Stress is rightly laid on the need for an adequate soil survey of the country. Much is already being done in New Zealand and appropriate methods are being worked out: meanwhile the underlying principles are being studied at Rothamsted, Bangor, Aberdeen and elsewhere.

Dairy research comes in for a great deal of attention because, as Lord Bledisloe rightly points out, uniformity in the butter and the cheese exported to Great Britain is an essential condition of their saleability and stable reputation in British

* Copies of the lecture can be obtained from Messrs. Whitcombe and Tombs, Ltd., 3 Addle Hill, London, E.C.4, price 1s.

markets. Nothing has contributed more to the attainment of this desirable characteristic than the production of commercial 'starters' commenced in Denmark some forty years ago and now widely used wherever dairying has become a science. So much research has been done on the feeding of animals and so advanced is the good farmer's knowledge of this subject that, in Lord Bledisloe's view, "if the average human being knew as much about the feeding of himself and his children as the average farmer knows about that of his stock, the average standard of human health and physical energy would be at least 33 per cent higher than it is. Probably as much as 50 per cent of the therapeutic activities of physicians, druggists and clinics is referable, directly or indirectly, to avoidable dietetic indiscretions based on ignorance of the fundamental principles of animal nutrition".

This statement is supported by some remarkable evidence. It is stated, for example, that the Plunket or Truby King system of feeding infant children has reduced the New Zealand rate of infant mortality under twelve months from 80 per 1,000 in 1889 to 32 per 1,000 in 1932, a figure which gives New Zealand the best record in the world and compares with 71 per 1,000 in England and Wales, 109 in Germany and 124 in Italy.

The chief export from New Zealand is wool, and no small part of the present depression in New Zealand is due to the low prices now obtained owing to the quantity of this commodity on the market; every penny per pound of wool sold represents £1 million in the national revenue. Naturally New Zealand is deeply interested in the research work on wool now going on in Great Britain: the search at Leeds for definite standards of grading which would enable the manufacturer to tell the farmer exactly what types of wool he wants; the studies at Edinburgh of the inheritance of the more important characteristics of the wool; and the Rowett Institute investigations on the relation between the composition of food and the yield of wool.

Next in importance to wool, and probably of more significance for the future of the country, come the dairy and meat industries, both of which ultimately depend for success on low temperature transport. Great Britain will probably always be New Zealand's best customer and the journey will always have to be across the equator; however much it may be shortened, there will always be the need for low temperature transport and storage. Research on this subject is now being taken up seriously and scientifically at Cambridge and elsewhere, and further developments may be expected in the near future. It is very gratifying to observe how much of the work that made so strong an appeal to Lord Bledisloe's highly skilled audience had been done in the agricultural research institutes of Great Britain.

The address is important not simply because of its subject matter, but much more because of its significance. The British Empire was founded by adventurous soldiers and sailors; it was developed by courageous farmers and settlers who, often struggling against fearful odds, brought the land into cultivation, built roads, railways and cities, and laid out the countryside as a vast agricultural estate. It has been knit together by bonds of sentiment steadily growing among the people and fostered by wise statesmen, writers and teachers. But the lands of the Empire have nowhere reached the limits of their development. The first feeling of an agricultural expert in visiting any of the great dominions is one of wonder at the vast natural resources still awaiting development.

Courage and hard work have played and must continue to play their part; science has now come in, vivifying with magic touch many an enterprise that seemed beyond hope, and achieving tasks which but a short time ago would have been deemed impossible. No one can tell where the applications of science will stop; for the present, the one thing certain is that they will go on at an increasing pace, playing an ever-growing part in the lives of all who are so directly dependent on natural forces as are the agricultural communities of the dominions. The Empire builders of to-day are the men and women who in Great Britain and overseas are quietly studying the scientific problems that so deeply concern the comfort and well-being of those living in the distant lands.

The change has far-reaching consequences. More and more it is becoming essential that the administrator should have a full appreciation of the part that science should play in the life of the community. Lord Bledisloe's undoubted success in New Zealand is due in no small measure to the fact that he recognises the value of science and so is able to enter more sympathetically into the life and problems of the Dominion than would otherwise be possible. The Cawthron address of this year may well be a significant portent.

The Science of Society

Societal Evolution: a Study of the Evolutionary Basis of the Science of Society. By Prof. Albert Galloway Keller. Revised edition. Pp. ix+419. (New York: The Macmillan Co., 1931.) 12*s.* 6*d.* net.

ONE of the most vital and important contributions that science can make to modern thought must surely be in the realm of social science, of sociology, or the science of society—to use the older term now adopted by Yale University. The question of its exact definition and scope, or of its relations with other kindred sciences, such as economics, history, anthropology, politics, psychology, ethics, is of small moment compared with that of making a really worth while contribution to the solution of at least some of the problems of modern civilisation.

The most hopeful line of approach hitherto has been along the lines of evolution as applied to human society. This, however, has been found to be a much more difficult and complicated matter than, in the first flush of Spencerian enthusiasm, was anticipated; and even with the powerful aid of Benjamin Kidd all difficulties were by no means cleared away. The complexity of the subject is strongly emphasised in the remarkably able book by Prof. A. G. Keller under notice, in which the attempt is made to give sociological study a fructifying definite orientation, similar to that given by Darwin in biology. The author insists that the "reasoning by analogy" of previous writers on social evolution has been vague and largely futile. There is, in human society, something more than mere analogy to organic evolution: there is real and specific variation, selection, counter-selection, transmission (in place of heredity) and adaptation.

Keller soon makes it quite clear that he does not identify evolution necessarily with progress. He find it next to impossible to define progress. At best we can only have adjustment. Man remains, physically, "unchanged in a changing environment" because he uses his brain and social organisation to make the necessary adjustments for tolerable existence. Such adjustments, often beginning with individual acts to meet special needs, confirmed by trial and error, and finally adopted by the social group, ultimately reach the status of convention, public opinion, mores, laws, and religious sanctions.

One of the first great principles of social science here emerges. All social action is controlled by convention. Yet, says Keller, this convention or custom is of such labyrinthine complexity and general pervasiveness that it is a difficult conception to handle, and its reduction to a more manageable shape by Sumner in his "Folkways" was a real *tour de force*. One can readily echo this high praise of Sumner's work even from the brief synopsis here given. The folkways of primitive society are likened to the cells of organic life. The mores are an advanced stage of folkways and include a judgment that they are conducive to societal welfare. Their origin, the rise of institutions, morals, law, and religion are described, and at the same time the scientific student is warned against

> "The philosophers, a term which must be understood to mean medicine men, prophets, law-givers, sages, theologians, and poets, who try to think out into general propositions of world philosophy, or of rights and duties in ethics, those views of welfare which the mores suggest. They want to bring the experience and theory of the mores into relation with the sweeping horizon of ghost-fear or mythology, or with general conceptions of the 'good', such as the advantages of courage, truthfulness, hospitality, and fidelity to the spoken word. This is what has been called 'thobbery', that is, thinking (wishfully) without interest in actual verification" (from an unpublished fragment by W. G. Sumner).

This is not too clear; but it is characteristic both of Sumner and Keller that they have no undue respect for 'great men' either in the classes noted above under the term 'philosopher' or any other class.

The agent of variation, which is constantly going on or being attempted, is the individual, often a 'great man' or several of these acting independently under a common stress or need. At any stage there are plenty of budding variations in the mores to select from. Ideas tumble over each other in the face of the need which evokes them. In any great crisis, even though world-wide as at present, there is no lack of ideas. The difficulty is to test, judge, select, apply. Experiments must be made. There is, however, says Keller, a kind of automatic regulation of this matter which resides in the process of societal selection.

The intricate processes and methods of selection, irrational and rational, and of counter-selection, the product of humanitarianism, are dealt with at considerable length. Selection is mainly effected

by the masses—the great bulk of the people with the supermen lopped off at the top and the defectives lopped off at the bottom of Sumner's turnip diagram. The Sumner-Keller view is that the masses are conservative, living on tradition and habit, the result of inertia. The folkways are their ways. They accept influence or leadership or new teaching, but not always in the form in which it is offered to them. They assimilate it slowly and with frequent modification. It is wrong to think they have any occult wisdom or inspiration by virtue of which they select what is wise, right, good. The 'great man theory', as expounded, for example, by Carlyle in his "Hero-Worship", is fundamentally different from, indeed it is the complete antithesis of, the views here expressed. Keller says the great man is merely the product of his time and its needs: he is only incidental. The results attributed almost solely to him would have come to pass in any case. He has had the luck, together with some natural endowment, to see and to some extent anticipate the impending changes. Another great principle here then emerges: the determining social cause of change is something very different from the human agency. "The latter is always secondary and relatively incidental and wholly ineffective by itself. To confuse the two is to miss essential truth. *The effective cause lies in the unpremeditated movement of the masses of men.*"

The difficulties are real enough and loom up mountainously, especially in connexion with those irresistible impersonal forces which Keller so often mentions and which, in his view, are the final arbiters of human destiny, though they originally seem to spring from the mores and are thus of human origin. Are they then so completely uncontrollable, irresistible, and impersonal?

Sumner says that the sound student of sociology can hold out to mankind as individuals or as a race only one hope of better and happier living. That hope lies in an *enhancement of the industrial virtues and of the moral forces which thence arise.* Industry, self-denial, and temperance are the laws of prosperity for men and States; without them, advance in the arts and in wealth means only corruption and decay through luxury and vice. The power of the human race to-day over the conditions of prosperous and happy living is sufficient to banish poverty and misery if it were not for folly and vice. This is splendid and should inspire a comprehensive plan of action for the present age. But have we in all this those arbiters of human destiny, those irresistible impersonal forces on our side? It would seem so; for Keller says that they invariably act in the direction of making the right adjustment, the one that is expedient for any particular time and environment. The old questions again arise: To what extent can man control his destiny, and how far can science alone go?

'The power of the human race' is a fine phrase. That power is undoubtedly greater than is often imagined. With this tremendous latent power awakened under the right stimulus, the urgent need, the national crisis, the faithful lion-hearted leadership, and with all the forces of the modern State, scientific, industrial and the rest, what could not a great nation accomplish, if, to all this, we add intelligent world co-operation? We find it a little difficult to reconcile these possibilities with those mysterious irresistible impersonal forces —resident in the masses—which yet work to human ends to the extent at least of making expedient adjustments. Nor do we think Keller quite appreciates the part played by the great man in history. There is doubtless much in what he says, but his examples here are not too happily chosen, and we still incline to the Carlylean view. Then again, as to progress, quite possibly from a strictly evolutionary point of view, we cannot necessarily expect progress. But yet, even at the risk of being guilty of 'thobbery', we must have some ideal at which we can aim, some sense of progress, or possibility thereof, for without this a science of society is going to be insipid. Perhaps the evolutionary point of view is inadequate. We think, further, that the author has underrated the potential hopes which reside in social experiment, in definitely planned policies of reconstruction and betterment. He says (page 205):

"This kind of thing (experiment and verification) may not be done in the domain of the social sciences, for the mores forbid man to experiment upon man. What goes by the name of social experimentation lacks rigor in its processes and emerges with vague and inconclusive results. The best the social scientist can do is about equal to the worst the natural scientist has to put up with: to wait on nature to perform quasi-experiments for him and to search history for those she may have performed."

The difficulties of social experiment are undoubtedly great, but does the above quotation adequately portray all that lies in this direction? It seems that it is precisely here that the greatest and highest hopes of social science must reside;

just here that it may hope to find means to rise to the rank of a true science based largely on experiment. The present writer has often reflected on the fair and stately prospects of an experimental sociology. In NATURE of Sept. 10, pp. 392–3, commenting on the excellent articles by Dr. Jacks and Prof. Miles Walker, it is stated that the time is opportune for courageous and adventurous experiment, and this is only too true.

The prospects of successful experimental methods are closely bound up with environment and the extent to which it can be controlled; but here Keller is comparatively silent. He says little about environment, though it is the supreme and all-important factor in evolution, especially in 'societal' evolution. In this latter it must differ in many fundamental ways from organic or natural environment. Among other things it should be more amenable to control, for example, slum-clearing. Many of the parts or items in environment are themselves subject to evolutionary processes. Keller observes, for example, that religion is a life condition of the first magnitude, yet he considers that, too, is subject to evolution. All this and much other vitally important and interesting matter could be discussed under the heading of environment. It is indeed as much deserving of a chapter to itself as variation or selection.

W. G. L. C.

Land and Fresh-Water Molluscs

Fédération française des Sociétés de Sciences naturelles : Office central de Faunistique. *Faune de France*. 21 : *Mollusques terrestres et fluviatiles* (première partie). Pp. 477 + viii + 13 plates. 22 : (deuxième partie). Pp. 479–897 + ix–xiv + plates 14–26. By Louis Germain. (Paris : Paul Lechevalier, 1930–31.) 150 francs each.

THE preparation of this work has involved a critical revision of the land and fresh-water molluscs of France, during which the author has made full use of the rich material at his disposal in the Museum d'Histoire Naturelle in Paris. One of the results of the revision is that a large number of species have been reduced to synonyms.

A short account of the anatomy of the gastropods and the lamellibranchs precedes a consideration of the characters of the shells and their anomalies and abnormalities. Passing to the faunistic section, the author distinguishes three principal associations of land molluscs—the hygrophilous, the xerophilous and the forest groups. The aquatic molluscs also fall into three series according as they live in running water, in quiet or stagnant water, or in large lakes. The most characteristic members of each of the six groups are named. In a short note on the molluscan fauna of the mountains the author states that the maximum altitude at which a large number of species live is known with considerable precision for the alpine region but less fully for the Pyrenees. Only a few terrestrial species, for example *Vitrina nivalis*, can exist under the severe conditions found at a height of about 3000 metres. This species disappears below about 2300 metres. Of the lamellibranchs, *Pisidium casertanum* is found in lakes at an altitude of about 2200 metres in the Pyrenees and up to 2500 metres in the Alps. For most of the species the author states the maximum height at which they have been found.

The molluscan population of France, which includes representatives of the majority of the European genera, falls into three groups—the southern, which is essentially Mediterranean in origin, the Atlantic or Lusitanian, and the northern, though these have not entirely preserved their individuality as migrations have taken place; for example, some of the Mediterranean species have migrated northwards even to the shore of the Channel. Lists of the characteristic species of the three groups are given. Useful observations on polymorphism precede the dichotomous keys to the 41 families of gastropods and the three families of lamellibranchs, to the genera and to the species which comprise the terrestrial and fluviatile molluscs of France.

Carefully devised dichotomous keys form a special feature of the "Faune de France" series and the present author has devoted much care to their preparation in this work. The characters of each genus and species are concisely but adequately described and notes are added under each species on the habitat, biology and distribution. The illustrations consist of twenty-six good collotype plates reproducing photographs of the shells of large or moderate size, and 860 text-figures of the small shells, considerably magnified, of characteristic details of shells and of the reproductive organs of the genera and subgenera of the gastropods. A bibliographical list (pp. 46) and a full systematic index are added. This work is commendable for its careful attention to the biology as well as to the systematics of the terrestrial and fluviatile molluscs.

Electrochemistry

Handbuch der Experimentalphysik. Herausgegeben von W. Wien und F. Harms. Unter Mitarbeit von H. Lenz. Band 12: *Elektrochemie.* Herausgegeben von K. Fajans. Teil 1: *Leitfähigkeit und Überführungszahlen in flüssigen und festen Elektrolyten.* Von Prof. Dr. L. Ebert und Prof. Dr. C. Tubandt. Pp. xvi + 496. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1932.) 45 gold marks.

THE last decade witnessed a violent revolution in our fundamental conceptions of the electrochemistry of solutions, in the course of which the classical theory of Arrhenius, postulating incomplete ionisation of strong electrolytes and constant ionic mobilities, was dethroned in favour of the Debye-Hückel theory, postulating complete ionisation with ionic mobility a function of concentration. In a sense, this revolution is still incomplete, since several important points in the Debye-Hückel theory are not yet satisfactorily developed and the original ideas of Arrhenius must still be called into service in connexion with weak and transition electrolytes, but remarkable changes have been effected in a domain where conditions were long regarded as settled and, after a great deal of natural hesitation in certain quarters, practically all the experts in the field have now reconciled themselves to the new regime.

The work under review offers a comprehensive account, both practical and theoretical, of the present state of affairs with regard to electrical conductivity and transport numbers in liquid and solid electrolytes, leaving electromotive force and polarisation for a second 'half-volume'. It is true that many portions of the field here covered have already been more or less satisfactorily treated in smaller separate monographs, but the difficulty of correlating these with one another has considerably diminished their usefulness, and awkward gaps in their alignment frequently rendered the original literature the only safe guide for the inquiring investigator.

The greater part of the book, naturally, is occupied with a discussion of the conductivity of liquid electrolytes. Methods of measurement, with all the modern refinements thereto, are described in detail, and the interpretation of the experimental results is systematically and simply presented. This section, together with the succeeding chapters on transport numbers in liquid electrolytes, is the work of Prof. L. Ebert of Würzburg. The concluding portion, which deals with conductivity and transport numbers in solid electrolytes, has been written by Prof. C. Tubandt of Halle, and is largely a description of his own important contributions to these very difficult topics.

It is interesting to note that the scope of the volume throughout is international rather than national, the contributions of British and American research workers being very generously acknowledged. Altogether, the volume is one which can be commended without hesitation to electrochemists of all ages and all stages.

JAMES KENDALL.

Blackwater Fever

Researches on Blackwater Fever in Southern Rhodesia. By Dr. G. R. Ross. (No. 6 of the Memoir Series of the London School of Hygiene and Tropical Medicine.) Pp. vi + 262. (London: London School of Hygiene and Tropical Medicine, 1932.) Paper, 8*s.*; cloth, 10*s.* 6*d.*

THIS report is the result of the work done by the author during his tenure of the Rhodesian research fellowship from April 1925 until April 1929. It is divided into three parts, the first of which is concerned with the epidemiology of the disease.

In a chapter describing the distribution of blackwater fever among the population of Southern Rhodesia, there is an interesting table which records the number of cases of the disease admitted to hospital and the number of fatal cases during each of the years 1914–28. The total cases numbered 679 and the deaths 152, giving a fatality rate of 22·2 per cent. It is significant that whilst the fatality rate varied considerably in different years, it showed no general tendency to decrease during the 15 years under consideration; in the four years, 1914–17, it was 24·2 per cent and in the last four years of the period, 1925–28, it was 27·9 per cent. These figures, which are by no means unique, might with great advantage be borne in mind by those who, being more highly endowed with optimism than with critical judgment, see fit to make extravagant claims for the success of particular lines of treatment based upon the observation of half a dozen cases or even, alas, of only one or two.

Part 2 is concerned with the changes in the blood and urine occurring in the disease. The author has rightly assessed the importance of

examination of these fluids in any investigation designed with the object of elucidating some of the many mysteries of blackwater fever. Much valuable information has been collected, but it is unfortunate that Dr. Ross was unable to make any quantitative estimations on the degree of hæmoglobinæmia during the passage of blackwater. The matter is of such importance for an understanding of the mechanism of the disease, and so many diverse statements, based frequently on careless and inadequate observations, appear in the literature of the subject, that new, and carefully made, quantitative estimations of the hæmoglobinæmia in blackwater fever are greatly to be desired.

On the all-important subject of the mechanism of suppression of urine in blackwater fever, the author writes as follows:

"One is thus forced to conclude that suppression cannot be entirely explained by the assumption that it depends principally upon the sodium chloride content and the acidity of the urine. If the phenomenon is to be explained by purely physicochemical reasons, the part played by other electrolytes present in the urine would seem to be equally important to that played by sodium chloride. It seems preferable to adopt the view of *Yorke and Nauss* (1911) that precipitation depends upon the degree of concentration of the urine and is facilitated by any factor which interferes with the secretion of water by the malphigian body. This may result from damage as a result of the excretion of the foreign protein hæmoglobin, from lowering of the blood-pressure, or for more obscure reasons."

In Part 3, which consists of clinical observations and of remarks on prophylaxis and treatment, the author discusses in some detail the question of the alkaline treatment of the disease. He writes that this method of treatment has received such extensive publicity that there is some danger of its being regarded as a panacea. Whilst he agrees with Baker and Dodds that in *in vitro* experiments precipitation of hæmoglobin takes place according to the conditions they describe, Dr. Ross considers that the time necessary for precipitation to occur makes it difficult to imagine such changes taking place during the passage of urine down the renal tubule. He favours the older view of Yorke and Nauss (1911), as stated above, that precipitation depends upon the concentration of the urine and is facilitated by any factor interfering with the secretion of water by the malphigian body. He is thus not inclined to favour the alkaline treatment more than any form of treatment which has copious diuresis as its object.

Dr. Ross is to be congratulated on an excellent piece of work, for not only has he made many valuable observations himself, but also he has collected together from an enormous and scattered literature the relevant observations of other workers; and he has brought the whole mass together into a single volume of moderate size wherein it is possible to discover the present position of knowledge on any of the many problems which this mystifying disease presents.

Short Reviews

Natural Varnish Resins. By T. Hedley Barry. Pp. xii + 294. (London: Ernest Benn, Ltd., 1932.) 42*s.* net.

ALTHOUGH we hear much of synthetic resins nowadays, the natural resins lose none of their importance in the industrial arts, and it is useful to have a comprehensive work on the subject by an author of such repute in the varnish industry. To some extent it is a development of a previous book, covering also the synthetic resins, by Barry, Morrell and Drummond, and the experience then gained has been used in bringing the present work thoroughly up to date. It is divided into two parts, the first, covering some forty pages, dealing with such general questions as the physical properties, solubility, constituents and chemical examination of resins. In the second part the individual resins are described at length.

Copious references are given to the original papers. The book is illustrated with maps and a considerable number of photographs. It is well produced, but the high price will tend to restrict its sale to industrial laboratories.

The salient facts as regards any particular resin relate to its origin and collection in different parts of the world, its analysis, and its chemical composition. The chemist has still a lot to do in elucidating the composition of these substances: they consist essentially of acids and neutral bodies, and their 'acid value' is one of the criteria applied to them. Some of them are phenanthrene derivatives, as, for example, pimanthrene from copal and retene from rosin, and a good deal is beginning to be established about the constitution of the resin acids. It is believed that in the tree they are built up by condensation of isoprene, which is now considered to be the basic building stone of so many plant products—the terpenes, rubber, carotene. In the past the chemist has studiously avoided in the laboratory all those reactions which led to the formation of resins, but the march of industry is forcing him both to study them and even to seek to imitate the tree in making them synthetically. Of course, the chief characteristic of the resins is that they are colloids,

and their diverse applications in the industrial arts are in virtue of this property.

The book makes no attempt to indicate, other than very briefly, the use of the resins, either individually or collectively. E. F. A.

(1) *Proceedings of the Second International Congress for Sex Research, London, 1930.* Edited by A. W. Greenwood. Pp. xi + 637 + 33 plates. (Edinburgh and London: Oliver and Boyd, 1931.) 21*s*. net.

(2) *The Conquest of Old Age: Methods to Effect Rejuvenation and to Increase Functional Activity.* By Dr. Peter Schmidt. Translated by Eden and Cedar Paul. Pp. xvii + 319 + 40 plates. (London: George Routledge and Sons, Ltd., 1931.) 21*s*. net.

(1) THE Second International Congress for Sex Research was held in London in 1930, when more than 250 members from about thirty different countries were present. Nearly all the papers delivered have now been published in the proceedings of the Congress. The editor has arranged them in five sections, biology, hormones, therapy, contraception and sociology. The majority of the papers deal with the physiology and biochemistry of the sex hormones and afford an excellent summary of recent work on this subject, since they are given *in extenso* with figures and tables, instead of in abstract as is more usual in the published reports of congresses.

(2) The other volume before us deals with only a small corner of the field of sex research, namely, the problem of rejuvenating the organism by stimulation of the internal secretion of the sex glands or by provision of this secretion from an external source. The author devotes a certain amount of space to refuting the criticisms which have been levied against the grafting of sex glands or the operation of vaso-ligature and also to attacking his critics. Perusal of the numerous case histories quoted shows the difficulty of maintaining a critical attitude in the evaluation of the results of the operations. It must, however, be remembered that all the functions of the body, and not the sexual alone, on which the emphasis is sometimes laid, are stated to be rejuvenated: thus digestion is improved, intellect functions more sharply and movements are brisker.

Both these volumes may be studied by those interested in the effects produced on the body by the most recently isolated hormones and in the therapeutic possibilities opened up by these investigations.

Archæology in England and Wales, 1914–1931. By T. D. Kendrick and C. F. C. Hawkes. Pp. xix + 371 + 30 plates. (London: Methuen and Co., Ltd., 1932.) 18*s*. net.

THIS book, the authors explain in their preface, is an enlarged English version of an article in German to be published under the auspices of the Romisch-Germanische Kommission of the Deutsche Archäoligisches Institut. Chapters have been added which deal with Roman and Anglo-Saxon antiquities.

The preparation and publication of this version was a happy thought, upon which archæologists will congratulate the authors, and for which they will be duly grateful. A critical survey such as this is useful as a reminder of how much fresh evidence has accrued during the last seventeen eventful years—and the amount is indeed considerable—and it serves to stimulate research by bringing into relief points upon which further evidence is required before anything approaching certainty in conclusion is attainable. For confirmation we need only refer to Mr. Kendrick's admirably impartial summary of the evidence available, at the time of writing, which relates to the earliest stone age industries in England. On the other hand, the considerable advances that have been made may be gauged—to take one example only—from the chapter on the 'Henge' monuments.

Of the twelve chapters into which the book is divided, Mr. Kendrick is responsible for Chaps. i–viii and Chap. xii, while Mr. Hawkes has written Chaps. ix–xi. The numerous illustrations have been chosen with sound judgment and a discrimination which has kept in view the needs of the text.

Astronomy. By Dr. F. R. Moulton. Pp. xxiii + 549. (New York: The Macmillan Co., 1931.) 18*s*. net.

THIS is an elementary textbook suitable for a general introductory course in descriptive astronomy, and differs from most books of a similar nature in the order of development of its subject and in its balance of emphasis. After introductory chapters on the constellations and telescopes, the earth is considered as an astronomical body. Its nature, motions, and problems connected with time, occupy three chapters, leading naturally to a consideration of the various bodies and phenomena of the solar system. All this occupies the greater portion (400 pages) of the book, and questions relating to sidereal astronomy or astrophysics (apart from solar physics) are relegated to the last two chapters.

The brevity and necessary condensation in the final section leads occasionally to an unfortunate obscurity of style. It also, however, allows other questions to be dealt with more fully than is usual in elementary textbooks; the chapters on gravitation and the evolution of the solar system, as well as parts of the final chapter on sidereal structure, being specially noteworthy in this respect. Nothing of fundamental importance is omitted, and many of the latest advances are well described, such as the discovery of Pluto, axial rotations of stars, and the new constellation boundaries (to a rough approximation). Apart from a few errors and minor blemishes, the illustrations (including numerous reproductions of photographs) form an attractively useful feature of the book.

Bronze Age Mining Round the Aegean*

By O. DAVIES

DURING the bronze age, Greece was remarkably wealthy in gold; though the most sensational finds have been those of Mycenæ, there is little doubt from the amount that has been turned up elsewhere that the contents of the shaft-graves only represent a small portion of the gold that was at one time available. Homer still has many lines reminiscent of the riches of Mycenæ, but seems no longer to be living himself in times of such plenty, and thus many of the gold objects which he describes are said to have been of foreign workmanship. In the early iron age gold was even rarer, as is seen by the astonishment of the Greeks at the regal wealth of a man like Crœsus. One may therefore ask oneself what happened to all the gold, seeing that only some of it seems to have been laid in tombs, and it is not possible for it to be destroyed by rust. Some may have been carried off by pirates, but if we look to the history of the period of reconstruction at the beginning of the iron age, we find two figures noted for their wealth, Midas in Phrygia and Solomon in Palestine; to Solomon may have gone some of the Aegean gold, brought originally to the Levant by the sea-raiders of the twelfth century B.C. or by Phœnician traders; and it is not unlikely that Midas made a good profit by selling to the Greeks the new metal iron before they had learnt to produce it for themselves, though it is probable that he also had gold mines of his own.

It is more difficult to decide where the Aegean peoples obtained their gold. The test by chemical impurities is unsatisfactory owing to the fact that gold, unlike copper, does not have characteristic impurities which are found in one mine but not in others. All the Aegean gold which has been analysed contains a good deal of silver, in amounts varying from 8 to 25 per cent, which suggests the use of native electrum; though some of the early gold, as the early bronze age pieces from Mochlos and Leucas, is of very good colour, there is no record of pure gold having been found in analysis, and in Egypt at least it is certain that the knowledge of purifying gold did not come in until later, probably at the time of the Persian invasion, while Crœsus probably started it in Lydia. On the whole, the late bronze age gold from the Aegean varies in colour, the more massive pieces being yellower than the leaf, which suggests that some method of faking the surface by dissolving the silver was already known, though it was not practicable for thin leaf.

As to mines, Macedonia seems to have been working a little stream gold from early times, as is seen by gold slags found on various sites. Herodotus[1] mentions the gold and silver mines of Siphnos in the seventh century, which were probably at H. Sosti; I have been told that two golden eggs were found here, ready to be sent as an offering to Delphi, but as they have now been lost this story must be considered doubtful. At any rate, stone hammers have been found in and above the mine, and I found a sherd which seemed to belong to some local sixth century ware, and a number of crucibles. Bronze age sherds, however, have not been found, and there are not many relics of the later bronze age on the island, so that it is probable that gold was not worked here until the iron age and that we shall not find here the source of the gold of Crete and Mycenæ.

To some extent probably local sources, which have since been exhausted, were used in the bronze age; for example, some gold objects have been found in Arcadia, not far from the placer of Doliana. Egypt produced much gold early, and, as there was frequent contact between it and the Aegean, gold may have been one of the articles of commerce. The placers of west Anatolia, especially Lydia, were probably not tapped much before the iron age, considering their wealth and reputation in later times. It may even be that the Danube valley was supplying Greece so early; it has been claimed that some gold found in Egypt came from Transylvania owing to the presence of tellurium*; and though the inference is not certain, since telluride of gold is reported from Andros, yet as there was for a long time a trade route from Egypt and Syria to the Danube, such a source is by no means unlikely.

The early bronze age objects of silver from Amorgos which have been analysed contain much gold and more copper than should remain in the metal after cupelling; they are probably therefore derived from native silver or a silver mineral. But a bar from Troy II and a vase from Mycenæ shaft-graves with a good deal of copper and some lead may have been cupelled badly or debased after cupellation.† The lead found is remarkably pure and almost free of silver, which makes it likely that it is derived from a mineral containing very little silver.

The Laurium mines perhaps were not opened before the seventh or sixth century; nor did they become prosperous until the discovery of the rich lower zone of mineralisation at the beginning of the fifth.[2] On Mytilene, at Argeno 1½ hours east of Molyvo, are old silver workings in which I found pieces of a black bucchero pot of the seventh or sixth century, now in the Ashmolean Museum. On Kuphonisia have been found some ancient mines for argentiferous lead with stone tools,

* From a paper read before Section H (Anthropology) of the British Association on Sept. 7.

* The antimony in this gold which was held to prove the presence of tellurium may be an early and sporadic instance of the use of stibnite for de-silvering, a technique otherwise thought to be medieval.

† *The presence of a little lead in silver is no convincing proof that cupellation had been practised; cf.* Friend and Thorneycroft, *J. Inst. Metals*, 41, 105, 1929, who do not believe that cupelling was known in Greece so late as the seventh century; only the knowledge of cupellation must precede that of liquation, which probably accounts for the large quantities of lead found in the iron age *aes rude* in Italy.

which may therefore be quite early, though the use of stone hammers is not confined to the bronze age.[3]

Other early silver mines are not known in the Aegean[4] nor is silver common early in Egypt, but there is much in Anatolia. The date of the old mines near Hector's grave in the Trojan Plain[5] is exceedingly doubtful. Balia was perhaps working early, but the mention in an alchemical author of silver from Adramyttium suggests rather a late date. Silver mines are known at Myndus, but classical writers are silent about them, and the modern name Gümüslü suggests that they are Byzantine or medieval.[6]

Farther east, there is certainly very early silver mining in Taurus at either Bulgar or Bereketli Ma'den; the Kara Öyük tablets mention the export of silver from this region in the third millennium. In Homer[7] we read of Halybe as the birthplace of silver; this seems to be located on the eastward land route from Troy along the southern shore of the Black Sea. Such data as we have would point either to the Taurus mines, reached by a road which followed the coast to perhaps the Halys mouth and then turned inland, or to the mines of argentiferous copper behind Tireboli, which are certainly Greek though it is not known how much earlier they go. Again, the story of the golden fleece in Colchis suggests early mining activity in the south-eastern corner of the Black Sea.

The copper of the early bronze age in Crete and the Cyclades seems to be almost entirely free of nickel but usually contains small quantities of lead, arsenic and antimony, while arsenic is sometimes added to colour the surface. These characteristics remain, on the whole, constant throughout the bronze age in Crete, but so far as one can judge from the scanty analyses of mainland objects, the metal contains only lead, arsenic and antimony being rare impurities.

Of the ores which have been analysed, that from Chrysokamino near Pachiammo was not tested for impurities, while that from Gavdos is incomplete but seems to contain about the right amount of antimony and arsenic. The Othrys ores have no nickel and contain little if any antimony and arsenic, though most have a small quantity of lead.

If we compare Aegean copper with that of neighbouring regions in the bronze age, we find that the Italian and Anatolian seem to correspond most closely to it. Analyses of ores from these regions are rare; that from Boccheggiano seems to contain rather too much silver, bismuth and nickel but otherwise agrees fairly well. The ore from Sacili in Macedonia is very similar to Aegean copper, but the mine is small, and I do not think it possible that it can have supplied the whole Aegean for fifteen hundred years; Othrys might also suit. On the whole, the analyses seem to show a constant source for copper in Crete throughout the bronze age, though the mainland copper is more variable and occasionally contains nickel. We shall see that it is probable that the mainlanders exploited a number of local mines of small importance, so that the compositions of their metal are likely to vary considerably.

To turn to the sites of mines known, I have found in the early bronze age stratum at Volo some copper slag, which I have described elsewhere. The numerous copper mines of Othrys were being worked in Hellenistic times, and for most of them there is no earlier evidence, while prehistoric sites in this area are infrequent; but some bronze double axes and celts were found in a mine at Gardiki[8]. Further, the hoard of ingots shipwrecked at Cyme might suggest the transport of copper from the mines of Othrys to southern Greece rather than the other way, it being by no means certain that these quadrangular ingots come from Cyprus. But it is difficult to say how important Othrys was in prehistoric times as a centre for copper production.

There is a persistent tradition in the ancient authors of a mine of copper and iron at Chalcis, and of an early metal industry there. One can scarcely believe that these stories are a mere invention due to the name of the town, though modern travellers have been unable to locate the mine. I have searched the territory of Chalcis thoroughly, without success; but the most likely locality is in the serpentine ridge just behind the town, which is now partly built over, and in which the mines would have soon been inundated if they had reached any depth. I have found stray pieces of copper slag to the south-east of the town; but the fact that no slag heaps of any size are known makes it probable that the mine was small and only working for a short period.

At Athens I have found pieces of copper slag on the slopes of the Acropolis, with a fragment of crucible which is perhaps early or middle bronze age. This probably comes from the working of some very small deposit; for example, malachite is reported at Colonus and on Ardettus, but the extent of the modern town makes adequate exploration of these sites now impossible.

At Mycenæ, apparently in late bronze age levels, copper slag has been found, and there is in the Athens Museum a tray of malachite galena and sulphur, which was found during Tsoundas' excavations here; unfortunately, it is not recorded where he found it. On both sides of the pass from Mycenæ to Phlius is a little copper ore; I could not find signs of ancient working, but a small opencast might easily be denuded completely or a shaft be filled in. Just above the deposit is a site with rough sherds which looked like early iron age ware. Other mines are reported behind Mycenæ; on the path to the Heraeum are several caves, one of which seemed to have been cut out with a pick, though whether as a mine or shelter I could not tell, while in another was a slight stain of malachite in the conglomerate. This information is at present unsatisfactory, but it is not unlikely that Mycenæ was an important centre of copper working during part of the bronze age.

On Seriphos there is much copper slag and a number of galleries in the iron mine which may have been seeking veins of copper; such rejection of the iron ore might point to early working, though there is some evidence that mining was being practised here in the later centuries B.C.

On Paros, copper slag was found in an early bronze age tomb at Abyssos. Near Naussa is a small mine of malachite, much overgrown, with a gallery leading off at each end; all the ore had been removed, as is usual in prehistoric mines; but otherwise the evidence for its early date is weak.

On the early bronze age acropolis of Syra a piece of copper slag was found.

The cave of Chrysokamino has yielded early and middle bronze age pottery, and was probably a copper mine, though all the ore has been extracted; slag, burnt clay and pieces of perforated crucible have been found outside. Gournia nearby was probably a manufacturing centre, considering how many moulds it contained, but Chrysokamino is too small to have supplied the whole of Crete with copper during the bronze age.

The copper mines of western Crete which are claimed as prehistoric were opened in Hellenistic times and continued until the Middle Ages. Much copper ore is also reported from Gavdos, but there is no reliable information as to when it was worked.

As to more distant sources, the direct evidence for bronze age mining in Cyprus is not strong, and it must be considered doubtful if the island supplied copper to the Aegean so early. The mines of Sinai are doubtful, the ore being apparently always poor, and it is likely that such copper as was produced was largely absorbed by the Bedouins, save at the times of Egyptian expeditions. The Kara Öyük tablets mention copper as an object of trade, but it is not common in western Anatolia. Italy seems to have been working copper sporadically from early times, and the Homeric Temesa is probably to be sought in this direction, whether Etruscan or south Italian ores were used. Largely, however, the Greeks seem to have used small local deposits which they completely exhausted.

Electrical and Magnetic Units

THE British Association has done a great service to the electrical industry by fostering the study of electrical standards and it was with considerable interest that Section A listened to two papers given by Sir Richard Glazebrook at the recent York meeting. Sir Richard has been an active member of the British Association committee on electrical standards which has laboured for a period of fifty years. In 1913 a single volume edited by Sir Frank Smith was published, giving the complete series of thirty-nine reports. Sir Richard was present at the York meeting in 1881 when Section A met at the same centre—St. Peter's School—and received the eighth interim report of the committee for constructing and issuing practical standards for use in electrical measurements. One of the papers* presented by him at the recent meeting showed the changes which have taken place in the British Association wire resistance coils over the period of half a century. The conclusion reached is that platinum is the most stable material to use for the construction of standard coils. This paper has already been referred to in NATURE (Oct. 22, 1932) and will be published in full in the Report of the British Association for 1932. The other paper† dealt with a topic which is still under discussion, namely, the definition of electric and magnetic units.

Sir Richard Glazebrook is president of the Commission of the International Union of Pure and Applied Physics which was set up by the General Assembly at Brussels in 1931 to consider the symbols, units and nomenclature used in physics.

The Commission at its first meeting decided that the most urgent problem awaiting solution was the definition of electrical and magnetic magnitudes. The first step taken therefore was to prepare a questionnaire which was circulated to the national committees working under the auspices of the Union of Physics in various countries.

The principal issues raised by this questionnaire related to:

(1) The basis on which a connected account of electromagnetic phenomena should rest. Should the starting point be Coulomb's law of force between magnetic poles or some other physical law?

(2) Should μ (the permeability) be treated as a quantity having dimensions in length, mass and time, or as a pure number? In other words, are H, the strength of a magnetic field, and B, the magnetic induction, quantities having different dimensions or are they quantities of the same kind?

The British reply to this questionnaire was agreed to at a meeting held in the rooms of the Royal Society in May last, at which were present, besides the members of the National Committee for Physics, representatives of the British Association Committee dealing with Magnetic Units and British representatives of the International Electrotechnical Commission, which had also been dealing with this matter.

* Material Standards of Resistance: the British Association Coils, 1881–1932. By Sir Richard Glazebrook and Dr. L. Hartshorn.

† Electric and Magnetic Units. International Congress of Electricity, Paris, July, 1932. By Sir Richard Glazebrook and Dr. Ezer Griffiths.

The British view is that:
(1) Coulomb's law is acceptable as a starting point.
(2) Permeability should be regarded as a quantity having dimensions.

Meanwhile, replies to the questionnaire had been received by the Commission from national committees abroad and from individuals; many of the latter submitted memoranda running into fifty typed pages. To advance matters a stage further it was decided to take advantage of the presence in Paris of a number of experts attending the Electrical Congress, to call an informal conference. This conference was attended by: Sir Richard Glazebrook (chairman), Prof. Wilberforce, Dr. Ezer Griffiths (secretary), all of Great Britain; Profs. Abraham (secretary of the Union of Physics), Fabry, Paul Janet, Brylinski, Cotton, P. Bunet, Lienard (France); Prof. Verschaffelt (Belgium); Profs. van Staveren and van de Well (Holland); Prof. Wallot (Germany); Prof. Lombardi (Italy); Prof. Bjerknes (Norway); Profs. Kennelly and Pender, and Dr. Curtis (United States).

The conference had before it a summary of the replies received to the questionnaire and after consideration of these a series of proposals were submitted by the chairman. Some of these proposals were accepted unanimously and on others an informal vote was taken.

It was unanimously agreed that:
(1) Any system of units recommended must retain the eight internationally recognised practical units: joule, watt, coulomb, ampere, ohm, volt, farad, henry.
(2) The C.G.S. system is suitable for the physicist.
(3) A system of practical units, including the above eight quantities, can be derived from these by multiplying the C.G.S. unit by appropriate powers of 10.

One important proposition before the Conference dealt with the basis on which to build any system of magnetic units.

Should a start be made from:
(*a*) the force between two poles (coulomb).
(*b*) the force between two current-carrying elements (ampere) or
(*c*) the idea of 'flux'?

There was no decided majority in favour of any one of these. The view expressed by the British Committee was that the force between two elementary magnetic poles provides the most satisfactory basis. On the other hand, a number of French physicists were in favour of taking the force between two elements of current as the basis.

The chairman explained the system formulated by Maxwell, but with the proviso that μ_0 and K_0 are both quantities having dimensions.

MAXWELL'S SYSTEM

$$\text{Force} = \frac{ee'}{K_0 r^2} \quad \cdots \quad \cdots \quad (1)$$

$$\text{Force} = \frac{mm'}{\mu_0 r^2} \quad \cdots \quad \cdots \quad (2)$$

$$\text{Force} = \frac{m\, i \sin\theta\, ds}{A\, r^2} \qquad (3)$$

$$\text{Where } \frac{A^2}{\mu_0 K_0} = (\text{Velocity})^2$$

This velocity is shown by experiment to be the velocity of electromagnetic waves. Also A is a constant for all media. Maxwell puts $A = 1$ and alternatively:

$K_0 = 1$ Electrostatic system.
$\mu_0 = 1$ Electromagnetic „

In a vacuum we are to have

$$F = mm'/\mu_0 r^2$$

and in any other non-magnetic medium

$$F = mm'/\mu_1 r^2$$

where μ_1 is characteristic of the medium.

For such media we have for the magnetic induction B_0 or B_1

$$B_0 = \mu_0 H. \qquad B_1 = \mu_1 H.$$

where H is the strength of the magnetic field.

$$\text{Hence } B_1 = \frac{\mu_1}{\mu_0} B_0 = \mu B_0$$

where μ is the specific permeability: a non-dimensional quantity given by the ratio μ_1/μ_0.

In a magnetic medium we have $B_1 = \mu_1 H$ but in this case μ_1 is no longer a constant; its value is given by $\mu_0 (1 + \frac{4\pi I}{\mu_0 H})$, where I is the intensity of magnetisation and H is the field strength measured by the force on a unit pole placed at the centre of a long narrow tunnel-shaped cylinder with its axis parallel to the lines of magnetisation.

The alternative (*b*) is referred to as the *electrodynamic system*; in this, following Ampère's equations, (2) and of (3) of Maxwell's system referred to above are replaced by

$$\text{Force} = i'ds' \int \frac{[r\, i \sin^r\theta\, ds]}{r^2}$$

or possibly

$$\text{Force} = \mu_0\, i'ds' \int \frac{[r\, i \sin^r\theta\, ds]}{r^2}$$

Each equation represents the force on an element $i'ds'$ due to a closed circuit of which ds is an element carrying a current i. The expression in the brackets represents a vector in a plane perpendicular to r and ds and these vectors are to be compounded vectorially.

The other suggestion (*c*) is that a system of units should be based on magnetic flux. The space inside a hollow anchor ring over the surface of which is wound a single layer of wire carrying a current, is found by experiments with iron filings or a magnetic needle to be in a peculiar condition, and the magnetic disturbance at each point within the ring has not only a direction but also a magnitude. The disturbance is said to be in the form of flux.

Both the electrodynamic system and the system based on flux spring from a desire to avoid the

necessity of introducing the idea of an isolated magnetic pole.

Sir Richard Glazebrook in his paper to the British Association at York points out that an ammeter or a voltmeter depends for its effects on the forces between a current and a permanent magnet, whereas the object of both the systems (*b*) and (*c*) referred to above is to avoid reference to permanent magnetism. As he points out, we may measure a current by its electrolytic effects and having done so, its E.M.F. by the heat generated in a coil in a calorimeter. In practice, we have to connect the quantities so measured with the accepted units, the ampere and the volt, thus complicating our fundamental definitions with the value of the electro-chemical equivalent of silver, or, if preferred, hydrogen. He directs attention to those who object to Coulomb's law to Appendix C of the Second Report (Newcastle 1863) of the Electrical Standards Committee of the British Association. It is by Clerk Maxwell and Fleeming Jenkin and deals with the elementary relations between electrical measurements.

Those who favour the basis of the system of magnetic units as the force between the two elements of current were invited to put forward a consistent plan of a series of definitions of electrical and magnetic units.

Another topic which came up for discussion at Paris was—

"Are B and H quantities of the same kind and is their ratio μ a pure numeric ? Or should μ be treated as a dimensional quantity ?"

In submitting the point of view of the British National Committee that B and H are quantities not of the same kind, Prof. Wilberforce pointed out that B has been defined according to one method by Maxwell in the early part of his work when considering the electromagnetic system; later, when treating the possibilities of other systems, he defined B in a different manner. According to Maxwell's first method, B and H would be quantities of the same dimensions and according to his second method they would be of different dimensions. Until it can be decided what method of definition is to be adopted, it is impossible to state whether B and H are to be looked upon as quantities of the same kind. The British view is based on the more general method following Maxwell's later work. The view of the Dutch Committee is that B and H are quantities of the same kind.

In the course of the discussion, the chairman referred to the fact that he was one of the last surviving pupils of Maxwell and he felt convinced from recollections of Maxwell's teaching that he was of the opinion that B and H were quantities of a different kind. When a vote was taken, nine were in favour of treating B and H as quantities of a different nature, whilst three were in favour of regarding B and H as quantities of the same nature.

Another issue raised was whether the factor $4\pi/10$ be retained in the definition of magnetomotive force. One speaker remarked that if one omits 4π in one place it occurs elsewhere. The consensus of opinion was against its omission.

EZER GRIFFITHS.

News and Views

Sir Frank Dyson, K.B.E., F.R.S.

SIR FRANK DYSON, Astronomer Royal, will terminate his official connexion with the Royal Observatory, Greenwich, on February 28. He went to Greenwich in 1894, when he was appointed a chief assistant. After retaining this position for ten years, he was appointed Astronomer Royal for Scotland. He returned to Greenwich after six years absence, being appointed as the successor of Sir William Christie. Throughout his career, Sir Frank has taken a keen interest in all the departments of the Observatory; it may perhaps be said that his greatest interest has lain in the determination of the proper motions of the fainter stars. In company with Mr. W. G. Thackeray, he made a careful re-reduction of the catalogue of faint stars observed by Groombridge at Blackheath a century earlier; these were compared with recent Greenwich observations, providing proper motions of several thousands of faint stars. The later Greenwich catalogues have all been planned with the view of the determination of proper motions for successive zones of the sky. Sir Frank has been a keen observer of solar eclipses, obtaining successful results in 1900 (Portugal), 1901 (Sumatra), 1905 (Tunis), 1927 (England); he wrote a paper in the *Phil. Trans.* for 1906, which is still regarded as providing the standard determination of coronal wavelengths. It was also under his auspices that the expedition went to Brazil in 1919 to test the Einstein shift of starlight. Both the magnetic department and the time-service have been revolutionised in recent years; the former was moved to Abinger, as the electric railways in London were a disturbing factor. For the latter, a series of Shortt clocks in air-tight cases give very precise results; also daily comparisons with other observatories are made by wireless signals. Sir Frank has considered his successor in obtaining the provision of a new reversible transit-circle, which is nearing completion. The present circle is eighty years old, and its shutters are too narrow, not permitting free circulation of air.

Dr. H. Spencer Jones, F.R.S.

DR. HAROLD SPENCER JONES, His Majesty's Astronomer at the Cape, has been appointed Astronomer Royal in succession to Sir Frank Dyson, and will commence his duties next March. Dr. Spencer Jones is well-known at Greenwich, for he went there in 1913 and served for ten years as chief assistant. The study of optics is one of his favourite pursuits;

during the War he gave much time to testing lenses that were required for military purposes. He observed the solar eclipse of 1914 in Russia, and went to Christmas Island for that of 1922, but it was cloudy. He has been ten years at the Cape and has made a very careful study of the motions of sun, moon and planets; he has discussed the lunar elements both from the meridian observations and from occultations, of which a great number have been observed. He is also a keen spectroscopist, and has contributed many papers on Nova Pictoris, deducing its distance from the rate of expansion of the nebulous envelopes. The heliometer measures of the planets, inaugurated by Sir David Gill, have been continued, and will shortly be published. Prof. de Sitter testified, in his discussion of the satellites of Jupiter, to the value of the results obtained with that instrument. A reversible transit-circle has been in use at the Cape for many years, of somewhat similar type to the new Greenwich instrument; experience with it will doubtless be of service to Dr. Spencer Jones at Greenwich. He will also find the new Yapp reflecting telescope nearly complete.

Dr. J. Jackson

DR. J. JACKSON, chief assistant at the Royal Observatory, Greenwich, has been appointed H.M. Astronomer at the Cape Observatory in succession to Dr. H. Spencer Jones. Dr. Jackson hails from the University of Glasgow, and went to Trinity College, Cambridge, where he was a scholar from 1909 until 1914, and made researches in dynamical astronomy, particularly the perturbations of Jupiter's eighth satellite. He became chief assistant at the Royal Observatory, Greenwich, in October, 1914, where he took a considerable part in the observing activity of the Observatory. He served with the survey section of the Royal Engineers from December, 1917, to the end of the War. Attention may be directed to Dr. Jackson's work on double star orbits and the determination of hypothetical parallaxes with Mr. Furner; to the very interesting results he obtained from his study of the Shortt clocks; and to his determination of the constant of nutation from observations with the Cookson telescope. During the last seven years, he has co-operated with Dr. Knox Shaw and Mr. Robinson in the reduction of Hornsby's observations at the Radcliffe Observatory, Oxford. Quite recently he has published corrections to the orbit of Mercury for the epoch 1774–98. These results are of special importance as they confirm the motion of the perihelion of the planet, discovered by Leverrier and explained by Einstein. With Prof. F. J. M. Stratton he edited vol. 5 of the collected works of Sir George Darwin. From 1920 until 1927 he was editor of the *Observatory* magazine, and was secretary of the Royal Astronomical Society from 1923 until 1929.

Boyle Medal of the Royal Dublin Society

THE council of the Royal Dublin Society at its meeting on December 15 decided, on the recommendation of the Committee of Science and its Industrial Applications, to confer the Society's Boyle medal on Prof. Paul A. Murphy, professor of plant pathology at University College, Dublin, for his important contributions to plant pathology. Prof. Murphy's researches on the fertilisation, cytology, and life history of the potato blight (*Phytophthora infestans*), and his investigation on the infection of the new by the old crop, have been at once an important contribution to pure science, and an advance of high economic value. He early recognised the economic importance of mosaic virus, and pointed out the close connexion between the deterioration of new varieties and their infection with virus. He also established the compound nature of mosaic and recognised the fact that the disease might be transmitted by symptomless carriers. This knowledge has greatly facilitated the finding and propagating of virus-free plants. His researches have also very materially increased our knowledge and means of control of onion mildew (*Peronospora Schleideni*) and of dry rot in swedes (*Phoma lingam*).

Native Lands in Kenya

ON December 20 question was raised in the House of Commons by Sir R. Hamilton as to the situation which has arisen in Kenya in regard to native rights in the land and the leases which are to be granted by the Crown for mineral development in the new goldfield in the district of Kakamega and elsewhere. Certain amendments to the Native Lands Trust Ordinance have been embodied in a Bill which was read for a second time in the Legislative Council of Kenya on December 21. Under these amendments, it is proposed to exclude temporarily from a native reserve, land leased for mineral development, without the provision of an equivalent area of land in exchange and without the requirement of notice to the local native council concerned. Sir R. Hamilton asked whether these proposals were made with the approval of the Secretary of State for the Colonies, and further, whether the amendment of the Native Lands Trust Ordinance had been considered by the Morris-Carter Commission. In his reply, Sir P. Cunliffe-Lister stated that not only had the provisions of the Bill been agreed to both by the Morris-Carter Commission and by the Central Lands Trust Board, but that he was satisfied that the arrangements for compensation and consultation provided ample safeguards for the interests of the native occupants of the area in question.

THE Secretary of State justified his approval of the amendments on the ground that they are necessary, as an interim measure to deal with immediate practical difficulties which might operate to retard the development of valuable minerals; while provision has been made for compensation in the form of a money payment. His statement that the development of the goldfield would be for the benefit of the native was repeated by the Chief Native Commissioner when introducing the amendments in the Kenya legislature; but he candidly admitted that they would be unpopular with the natives. That admission was an understatement of the case.

If these amendments become law, of which at present there seems every prospect, the outlook is indeed grave. No limit can at present be set to the area which will be affected by the exploitation of mineral rights. Difficulties have arisen when compensation has been given for expropriated native rights in land in the form of substituted areas. The consequences of a money payment in its effect on tribal feeling and on tribal character will be serious. To divorce the native from his land, which to him is sacrosanct, is to incur the risk of causing unrest and creating a native problem no less, and possibly even more, serious than the problem of the detribalised native in South Africa. Matters should not be allowed to rest here.

Imported Books in Australia

EARLY this year (NATURE, Feb. 20 and April 2), we commented on the unfortunate effect on scientific and educational progress in Australia likely to be produced by the primage duty and sales tax on books, periodicals and magazines. We welcome, therefore, the announcement made on November 10 in the House of Representatives by Mr. Lyons, the Prime Minister, that these taxes are to be abolished (*Sydney Morning Herald*). They were introduced, with much other taxation, as part of the emergency measures necessary to meet the financial situation in Australia. A duty of 10 per cent on imported books and a sales tax of 6 per cent, together with the depreciation of Australian money, was clearly a heavy burden for scientific workers and others anxious to keep abreast of the times to bear, and an influential deputation waited upon Mr. Lyons asking for the remission of these taxes. As we pointed out at the time, and also when the Import Duties Bill proposing a duty of 10 per cent on goods imported into Great Britain was before the House of Commons, the revenue to be expected from the taxation of scientific literature in particular is negligible; such duties increase the cost of research and thereby hamper progress. Now that the budgetary position in Australia has improved to the extent that reduction of taxation can be considered, we are glad to find that the abolition of the primage duty and sales tax on literature is in the first group of measures brought forward.

Jubilee of the Basic Steel Process in France

THE basic steel process was introduced into France in 1882, and to mark the fiftieth anniversary, a special meeting of the Société des Ingénieurs Civils de France was held in Paris on December 5, the President of the Republic, M. A. Lebrun, honouring the proceedings by presiding. Four addresses were given dealing with the history of the basic process, and another on the iron ore district of Lorraine. The Iron and Steel Institute was represented by the president, Sir Charles Wright, Mr. F. W. Harbord and Mr. G. C. Lloyd, who prior to the official proceedings were received in private audience at the Palais de L'Elysée by the President of the Republic. The basic steel process which made possible the utilisation of huge deposits of hitherto practically useless phosphoric ores, was the invention of Sidney Gilchrist Thomas (1850–85) who worked at the subject while a clerk in a London police court. His first paper, written in collaboration with his cousin Percy Carlyle Gilchrist, "On the Elimination of Phosphorus in the Bessemer Converter" was to have been read at the Paris meeting of the Iron and Steel Institute in 1879, but for want of time had to be omitted. Thomas, however, was brought into contact with E. W. Richards and then J. E. Stead, and a successful demonstration of the process was made on April 4, 1879, at the Cleveland Steel Works. Thomas unfortunately did not live long to enjoy his triumph, for after travelling in search of health, he died in Paris on February 1, 1885, and was buried in the Passy cemetery.

Education and International Organisation

THE report of the Sixth Committee to the Assembly of the League of Nations on the work of the International Organisation for Intellectual Co-operation stresses the importance of the educational questions with which the International Committee has been concerned, particularly those concerned with instruction in the aims and work of the League. Inquiries on the training of primary and secondary school teachers and the efforts made to facilitate the revision of school textbooks are of the greatest importance for the development of a spirit of world citizenship and the replacement of the partisan and nationalistic teaching of history and geography by a presentation alike scientific in method and worldwide in sympathy. Links are being created between university organisations and national educational information centres, and the report stresses the advantages obtainable from a new orientation of broadcasting and the cinema, with the assistance and guidance of teachers.

EFFORTS in the field of continuation courses and adult education have continued, while the research work on international relations, of which the report on the intervention of the State in economic life at the Milan Conference last May was the outcome, is being pursued, and the results of inquiries carried out in an objective and disinterested spirit will be discussed at a further meeting of men of science. Stress was laid on the work to be done by the Press in raising the intellectual level of mankind and a resolution adopted by the Assembly requests the organisation to study the methods by which the Press might contribute to a better understanding between the peoples of the world by perfecting their knowledge. Reference is also made in the report to the successful co-operation established with the Chinese Government to facilitate the extensive schemes of educational re-organisation drawn up by the latter, and the report of the mission of educational experts sent to China, like the report presented by a representative of the Educational Cinematographic Institute, embodies ideas regarding the establishment of a system of public education which should be of value to all governments.

Calakmul, Yucatan

FURTHER particulars of the recently discovered Maya city of Calakmul, in the south of Campeche, Yucatan, dated by its sculptured monuments as belonging to the Old Empire, A.D. 364–551, have been published by the Carnegie Institution of Washington (*News Service Bulletin*, vol. 2, No. 34). The information is derived from a report by Dr. S. G. Morley on the results of an expedition of the Institution which left Washington for Calakmul in April last. Forty-one additional monuments were discovered, bringing the total number up to 103, the largest number yet found on any Central American site. The dates on 45 monuments have been deciphered. Among the more notable discoveries were the quarry from which the stone was taken with two large blocks side by side, partially quarried, just as they were left by the builders, a huge flat outcrop of limestone in which were sculptured figures of six prisoners with their arms tied behind them by ropes and a large sculptured monument portraying a priest grasping a spear in his right hand, which was erected in A.D. 472. Owing to the luxuriance of the vegetation only a single building has been left standing. A survey map of the central part of the site, the civic and religious centre, has been made. The importance of the site lies in the fact that, lying half way between the earlier cities of northern Guatemala and the later cities of northern Yucatan, it fills in a geographical 'blind-spot' and bridges the gap between the two regions. It is within four days' journey by mule from Uaxactun, the oldest city of the Maya civilisation in northern Guatemala. The foundation of the city, or at least its attainment of sufficient economic importance to permit the inhabitants to mark the five year periods by the erection of monuments, would appear to coincide with the later part of the First Period of the Old Empire, when Maya culture was expanding throughout the Yucatan peninsula.

Paintings in Ancient Palestine

A DISCOVERY of special interest at Teleilat Ghassul in Palestine is reported by the Rev. J. G. Duncan in the current issue of *Ancient Egypt* (Pt. 3, 1932). On this site, which is conjecturally identified with the ancient Sodom, three buildings, evidently not temples or palaces, but dwelling-houses, have been brought to light which date, at the latest, from 2,000 B.C., when the city was finally destroyed. In two of them the room-walls proved unexpectedly large, being 19 ft. and 20 ft. in length respectively. It was not known previously that dwellings of this size were in use in Palestine at this early stage of civilisation. What, however, was of even greater interest was the fact that these walls had been decorated with paintings, a single subject covering the whole wall, thus arguing developed artistic skill. With the exception of a cistern at Ophel, attributed doubtfully to the Byzantine age, wall paintings had not been discovered previously in ancient Palestine. The paintings, which are on plaster, have suffered from various causes, including the damp soil, which may explain the apparent absence of wall-paintings on excavated sites. It is just possible to make out the subject of two of the paintings. One is apparently a religious scene and shows several, six or seven, human figures gazing towards a shining object in front of which stands a smaller figure, facing the others; and the second is a landscape or hunting scene, in which the only well-preserved figure is a bird, painted with a master's touch. The colours, light and dark red, brown in various shades, black, yellow and white are the same as appear in the painted pottery. The site, which is being excavated by P. Mallon, is somewhat obscure in its cultural and chronological relations. It appears to be of late neolithic or early copper age date.

Exhibition of Scientific Instruments and Apparatus

A PRELIMINARY announcement of the Physical Society's twenty-third Annual Exhibition of Scientific Instruments and Apparatus which is to be held at the Imperial College, South Kensington, on January 3–5 has already appeared in these columns (Dec. 10, p. 887). Particulars are given there of the times of opening and of the times and titles of the discourses. The catalogue of the exhibition, which is used by many as a reference book during the year, has now been published, and copies may be obtained from the Exhibition Secretary, at the office of the Society, 1, Lowther Gardens, Exhibition Road, London, S.W.7 (9*d*. post free). We are glad to notice that although the name of the Optical Society no longer appears on the catalogue, since it has amalgamated with the Physical Society of London, the optical instrument trade is as well represented as in former years. The Physical Society is making an important contribution to the scientific instrument trade by the inclusion of a section for apprentices and learners at the Annual Exhibition. The catalogue shows that the exhibits in the research and experimental section will be of great interest, and that the trade section, which forms the principal part of the exhibition, will include many important new developments. The value of the exhibition is enhanced by the excellent response of those taking part in it to the desire expressed by the organising committee, that the working parts of instruments or apparatus should be exposed to view. In some instances exhibitors have provided working models. We understand that the discourses to be delivered at the exhibition will be fully illustrated by experiments, lantern slides, and cinematograph films.

Floodlighting

THE floodlighting of many of London's famous buildings last year was a great popular success. It also gave engineers a unique opportunity of studying the problem critically. In a paper on the subject which appears in the General Electric Co.'s (G.E.C.) *Journal* for November, Mr. T. E. Ritchie begins a very thorough discussion of the subject. He shows the fallacy of thinking that floodlighting is objectionable because it is 'unnatural'. The same objection might be urged against the inside lighting or the warming of a building or even against the building

itself. In many cases, however, the way in which it is done is open to severe criticism. To illustrate this he shows photographs of Thames House, Millbank, floodlighted, first when special attention is paid to the roof and skyline and secondly when they are neglected. In the first case, the effect produced is beautiful but in the second case the floodlighting is very disappointing, the building appearing dwarfed and incomplete. The floodlighting in the first case was designed by Sir Frank Baines, the architect responsible for the building, and he supervised its execution. It is also pointed out what an important part the reflection factor of the lighted portion of the front of the building plays. In floodlighting the front of the Institution of Electrical Engineers, London, for example, the aggregate total load on the 26 floodlights used is 39 kilowatts. Owing to lack of time, the front had not been steam-cleaned prior to the installation and so the average reflecting factor was only 7 per cent. If it had been steam-cleaned, the average reflecting factor would have been increased about five times and so the saving, if the same total illumination were produced, would be about four-fifths of the present current bill.

Electric Cooking on the Thermal Storage System

SINCE coal can be produced at a uniform rate and stored ready for use as required, the plant necessary for its production has only to be capable of supplying the average demand. The same is true of oil and gas but not of electricity. Therefore the size of the necessary generating plant for electricity is fixed by the maximum and not by the average demand. As a rule the maximum output is about three times the average output and so most generating stations could treble their output provided the load was evenly distributed over the day and night. As capital charges usually represent an appreciable fraction of the selling price of electricity, any new demand which tends to level the load can be supplied economically at a reduced tariff. In thermal storage systems for heating buildings or for supplying hot water, use is made of this principle by supplying heat to the storage water at times of light load at a much reduced rate. In the case of electric 'cookers' using thermal storage, the problem is more difficult as the temperature required for cooking is much higher and the cost limits the use of too much thermal insulation. In an article on storage cookers in the General Electric Co.'s *Journal* for November, O. W. Humphreys and Dr. E. C. Walton describe different types of these devices used in America and various Continental countries as well as the 'magnet storage cooker'. Compared with the standard type of electric cooker, the latter has the following advantages. The cost of installation is very low as it is merely the cost of an extra lighting point in the house circuit. The cost of maintenance is also very low compared with the ordinary cooker, and no meter is required. When the electric supply is sufficiently cheap these cookers might well be used. Some are already in use in the Midlands in the homes of working-class people.

Research in Plant Industry in Australia

THE fifth annual report of the Australian Council for Scientific and Industrial Research shows that results of great economic value, far exceeding the total expenditure of the Council, have been achieved. Problems relating to the control of disease form one of the chief lines of investigation undertaken by the division of plant industry, and such outstanding success has been obtained in the control of bunchy top disease in bananas that it has led to the re-establishment of the crop on large areas. The heavy annual loss hitherto sustained from the development of bitter pit in exported apples should now be reduced to negligible proportions, since its relation to immaturity at picking time has been established. An additional activity of this division is the introduction from abroad of new varieties of plants likely to be of value, particularly in the drier districts. Following the success with which weed pests, such as St. John's wort, have been suppressed, the entomological division is extending the method of biological control to other noxious plants, and an appropriate insect for destroying the Noogoora burr having been recently discovered, on the completion of laboratory trials this fly will be liberated in the infested districts. The recently formed Division of Forest Products has carried out particularly valuable work on the seasoning of hard woods for the manufacture of cases, and has further devised a rapid and cheap method for treating wood to be used for butter boxes so as to avoid the development of taint, but although attention has been given mainly to problems of immediate importance, fundamental research has not been neglected.

Weeds of Grassland

IN spite of the increased attention paid to grassland farming in recent years, there is still a vast area of permanent grass of poor quality, and since the reduction of weeds is intimately associated with the best means for securing its improvement, the issue by the Ministry of Agriculture of "Weeds of Grassland" (prepared by H. C. Long, and published by H.M. Stationery Office, price 5*s*. net), should prove of great value. At the outset, emphasis is laid on the necessity for using clean seed when sowing land down to grass, as injurious weeds are readily introduced, and instances of the special dangers in the case of the rye-grasses and clovers are cited. The principles in eradicating weeds from grassland are those which make for general improvement in the herbage, and in many cases attention to drainage, manuring, grazing, etc., rather than direct methods of destruction (though spraying is considered), will lead to the eradication of undesirable species. A large number of the worst weeds that occur on grassland are dealt with individually, classification being made according to the natural orders to which they belong. A short botanical description, in which technical terms are so far as possible avoided, coupled with 92 illustrations (18 of which are coloured) from seeding to fruiting stages, renders identification a comparatively simple matter, and points of interest such as the association

of a weed with certain soil conditions, its possession of poisonous or other special properties, as well as the best methods for its eradication, are given in each case.

Salad Crops

THE growing of salad crops has become a highly specialised business in several parts of England and there seems no reason why the acreage devoted to this branch of horticulture should not be profitably extended. As an aid to growers, whether on a large or small scale, the Ministry of Agriculture has issued an illustrated bulletin (No. 55, H.M. Stationery Office, 1*s.* 6*d.* net), from which it is evident that with good management it is possible to have supplies for the market throughout the whole year. Lettuce is quite the most important crop that is included under the term salad, and the best methods for its cultivation in the field, in heated and unheated glass-houses or in frames, are described in detail. Some account is given of the varying methods adopted in different districts and the varieties found to be most satisfactory in each locality, while cultural methods in use in other countries such as America and France are also included. Watercress is another important crop grown for salad purposes. Although little difficulty is experienced in its cultivation, it is essential that the water in which it is grown should be of the highest quality as the industry has suffered considerable harm from cress grown in contaminated streams. Attention to local conditions and markets, and the choice of a suitable variety to meet these requirements, are also needed if the cress-growing is to prove a thoroughly profitable undertaking.

Forest Flora of Syria

AN expedition under the leadership of Dr. Alexander Eig, head of the Section of Systematic Botany and Ecology at the Hebrew University, Jerusalem, has been examining the forest and other flora of Syria (Science Service, Washington, D.C.). During the tour, the members of the expedition were able to collect valuable material for the herbarium as well as to complete plans for the Syrian Section of the new Botanical Garden at Mount Scopus. The party travelled twice throughout the length and three times across the width of Syria, and were able to fix in a preliminary fashion the line of demarcation between the Mediterranean zone and that of the Urano-Turanic region, the precise boundary between which was previously unknown. An important part of the expedition's work was a study of the forest species of Syria, and the investigations undertaken enabled the principal types of forest species, particularly in the Amanus and Cossus hill regions, to be determined. A study thus begun came to the knowledge of the French Governor of Jebel Druze. The expedition received great assistance from the French Government officials in the mandated territory north of the Sykes-Picot line, and the French Governor has asked Dr. Alexander Eig to advise on the subject of afforesting certain parts of the Jebel Druze region. The determination of the principal Syrian forest types will be, it is said, of considerable importance to the Botanical Garden on Mount Scopus.

Revision of Ordnance Plans

THE methods adopted in the field revision of the large-scale Ordnance Survey Plans, with some account of earlier methods, are described and explained in detail in a pamphlet by Capt. J. C. T. Willis ("An Outline of the History and Revision of the 25-inch Ordnance Survey Plans". H.M. Stationery Office. 2*s.* 6*d.*). The revision in the field is carried out by methods of prolongation and intersection but new detail must be 'hung' on to the original survey and not on to matter added at a previous revision. The use of specially selected points on the original survey has been abandoned and the equal reliability of all the original detail is accepted. The newest development adopted to counteract the liability of errors in redrawing the revised sheet entails the use of 'coated' paper at that stage. This paper permits all old detail to be expunged chemically, without affecting the surface of the paper beneath. Then it is found possible to avoid the redrawing of old detail, which involves a saving in accuracy as well as in time. A method of partial revision has had to be adopted in the centres of town and cities on the ground of economy. This neglects minor alterations in back premises while concentrating on the alignment and position of street fronts. The pamphlet contains a number of practical examples of revision, illustrated by charts, and discusses the kind of errors the surveyor may make.

Weather Maps showing Typical Distributions of Pressure

A PAMPHLET has been produced (Air Ministry: Meteorological Office. Examples of Weather Maps showing Typical Distributions of Pressure. (M.O. 237, second edition.) Pp. 8. (London: H.M. Stationery Office, 1932.) 3*d.* net.) to meet the needs of those schools where another publication prepared by the authority of the Meteorological Committee entitled "The Weather Map", which forms an introduction to modern meteorology, is used as a textbook for the teaching of elementary meteorology. The latter work appeared a little more than two years ago (see NATURE, 126, 755, Nov. 15; 1930). Being a comparatively expensive production (price 3*s.* net, compared with 3*d.* net in the case of the pamphlet under notice), it was regarded as unsuitable for distribution to individual pupils and accordingly six of the most important illustrative synoptic weather charts have here been selected from it so that pupils would be able with the pamphlet in front of them to follow the explanations of a teacher using "The Weather Map" as a textbook. The six figures selected are those numbered 9, 18, 21, 22, 23 and 24 in the textbook, and give typical examples of a depression, anticyclone, secondary depression, V-shaped depression, wedge and col. There is no explanatory matter beyond a paragraph describing the weather corresponding with the various letters that appear on the map (the Beaufort weather notation is used), the method of showing the speed and direction of the wind, the temperature, and—by means of isobars for 4 millibar steps—the distribution of pressure. The two publications, both

of which are to be obtained from H.M. Stationery Office, should, if used generally at schools, put young students on very familiar terms with the weather maps appearing in many of the leading newspapers, and at the same time give some idea of the methods of working of the official forecasters.

Atlantic Ice

THE work of the United States ice patrol on the Atlantic shipping routes during 1931 (International Ice Observation and Ice Patrol Service, 1931. Coast Guard Bulletin, No. 21) records a most unusual year. The normal number of icebergs coming south of lat. 48° N. during the year is 419; this is the mean of thirty-two year's records. During 1931 only 13 icebergs came so far south and ten of these were in May, which is the month of widest spread ice distribution on the Grand Banks. March showed two bergs and April one south of the 48th parallel. There is only one record of another year so free from ice—in 1924 only eleven bergs were recorded. These figures may be contrasted with more than a thousand in 1929, 1912, and 1909. The report contains the usual chart of the distribution of ice on the routes frequented by shipping and also the records of oceanographical observations. An interesting appendix gives an account of the ice observations made in the polar seas during the cruise of the *Graf Zeppelin* in July 1931 over the Barents and Kara Seas.

The North-East Passage

RUSSIAN newspapers have announced that an expedition on the ice-breaker *Sibirjakov*, under the leadership of Prof. Schmidt, has succeeded in navigating the whole length of the North-East Passage, from the White Sea to Vladivostok. The most dangerous section was found near the North Land, which the expedition rounded on the northern side, where it was necessary to blow up the ice in order to make any progress. The mouth of the Lena was reached in less than a month after leaving Archangelsk, but great difficulties were encountered between the mouth of Kolyma and the Bering Strait. Here the ice was three to four metres thick and all the blades of the ship's screw were broken one after another. After six days of strenuous work the ship's stern was raised above water by shifting the coal and the necessary repairs made, but when the expedition was only ninety kilometres from the Bering Strait, the screw was lost altogether, since the main axle broke, so that the remainder of the journey had to be made under sail.

Memorial to Dr. R. Stenhouse Williams

THE National Institute for Research in Dairying, University of Reading, has recently issued an appeal for funds to provide an appropriate memorial to the late Dr. R. Stenhouse Williams, first director of the Institute, who died on February 2, 1932. It has been decided to devote the fund chiefly to the further development of the Institute, to which Dr. Williams devoted all his energies. The signatories to the appeal, who represent dairy science in all its aspects, consider that this application of the fund will form a lasting monument to Dr. Stenhouse Williams. A small permanent memorial will also be erected within the Institute. Further information can be obtained from Mr. S. R. Whitley, "Rookwood", Shinfield, Reading.

M. Santos Dumont

ON December 21, the State funeral of Santos Dumont, the Brazilian pioneer of aviation, took place in Rio Janeiro. His death occurred on July 23 at São Paulo, and owing to the disturbed state of the country he was first interred there. On December 18, after the body had lain in state in the crypt of the Cathedral of São Paulo for some time, it was removed to the capital, where on arrival it was met by an escort of military and naval aircraft which performed evolutions during the transit from the station to the Cathedral of Rio Janeiro. The public were afterwards admitted to pay their last respects to one who is proclaimed by his country as the father of aviation, and on December 21 the final rites took place at the St. John the Baptist cemetery.

Announcements

MR. H. T. TIZARD, Rector of the Imperial College of Science and Technology, has been appointed chairman of the Aeronautical Research Committee in succession to Sir Richard Glazebrook.

THE Government of Ecuador has awarded the decoration of Al Merito, in the degree of Gran Oficial, to Dr. George Sheppard, State geologist to the Republic of Ecuador, in recognition of his valuable work in a consulting capacity to various departments of the Government, and also in appreciation of his published contributions to geological science during the past few years.

THE annual report of the Rockefeller Foundation for 1931 details the activities of the Foundation, of its grants in aid in various domains of human knowledge, scientific and humanistic, with brief reviews of the chief researches carried out under its endowment. Much work has been done on yellow fever, including trials of preventive vaccination. Under malaria, the existence of two races of *Anopheles maculipennis*, the chief mosquito-carrier in southern Europe, is described, one with barred, the other with dappled eggs, the former predominating in the non-malarious districts. The disbursements of the Foundation during the year amounted to 17,477,225 dollars.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A public analyst for the Metropolitan Borough of Fulham—The Town Clerk, Town Hall, Fulham, S.W.6 (Jan. 4). A principal of the Newport Technical College and Institute—The Director of Education, Education Offices, Charles Street, Newport, Mon. (Jan. 14). A University professor of civil engineering at the Imperial College (City and Guilds College) —The Academic Registrar, University of London, S.W.7 (Feb. 17).

Letters to the Editor

Glycogen in Cartilage

IN 1923 Robison[1] showed that when bones of rachitic rats were immersed in solutions of calcium hexose-monophosphate or glycerophosphate, a dense deposit of calcium was formed in the matrix of the hypertrophic cartilage at the site where calcium would have occurred *in vivo* if the rats had been fed on a normal diet. He showed that the deposition of soluble calcium salts as an insoluble phosphate of calcium was due to the activity of an enzyme, phosphatase, which he was able to separate from bone.

FIG. 1.—Untouched microphotograph of section through mandible and Meckel's cartilage in a human embryo of about 72 days. Stained with Best's carmine.
C.C.=senescent calcified cartilage of Meckel with 'hypertrophied' cells laden with glycogen.
O.T.=Osteogenic fibrous tissue in which osteoblasts are differentiating with discrete particles of glycogen.
B.=Lamella of membrane bone with osteoblasts serially arranged on the free surfaces.

Fell grew the isolated femora of six-day chick embryos *in vitro* and with Robison[2] proved that the enzyme is formed by or in the hypertrophic cells of the cartilage.

Phosphatases have been found not only in actively growing limb bones but also in other tissues of the body though these phosphatases are not all of the same type. They are normal constituents of the blood, occurring both in the corpuscles and in the plasma. Both corpuscles and plasma also contain hydrolysable phosphoric esters (Robison,[3] Kay[4]). Kay published a method for estimating the activity of the phosphatase in the blood plasma. He measured the number of milligrams of inorganic phosphate liberated from excess of sodium glycerophosphate in 48 hours at 38°C. and *p*H 7·6 by 1 c.c. of plasma. In the normal adult the average value is 0·15 mgm. Numerous papers dealing with the quantitative distribution of phosphatase have appeared. There is general agreement that in cases of generalised bone disease the phosphatase activity of the blood plasma is increased even to twenty times the normal, and that the increase is proportional to the severity of the disease. Robison and Kay have thus extended the fundamental problem of deposition of calcium and bone from an elusive inorganic reaction to a carefully balanced reaction involving inorganic radicles in combination with organic molecules as in the phosphoric esters, and controlled by an enzyme, phosphatase, which seems to be specific, within limits, in its action and subject to quantitative estimation.

Harden and Young[5] and, later, Robison had emphasised the part played by phosphatase in the fermentation of yeast in relation to a deposit account of glycogen and a circulating account of hexose-phosphoric esters. Meyerhof[6] and Embden[7] later depicted the metabolism of muscle in terms of glycogen, hexose phosphoric esters and a muscle phosphatase as distinct from the earlier conception of the breaking down of glycogen to glucose and lactic acid. They showed that only about one-fifth of the lactic acid formed in the process of contraction of muscle is oxidised directly to carbon dioxide, the remainder being retransformed through hexose-phosphate to glucose and glycogen in the presence of oxygen.

In view of the known facts with regard to the distribution of glycogen in association with the hexose-phosphoric esters and phosphatase both in yeast and in the muscle cell, it immediately occurred to me that the hypertrophic cells of cartilage should be examined for glycogen in the hope that the chemical system in the ossification process would bear some relation to that already described for cells so widely different as the yeast cell and the muscle cell. Accordingly human embryos and the embryos of various laboratory animals were examined for glycogen. The tissues were fixed in Allen's modification of Bouin's fluid, sectioned in paraffin and stained with Best's carmine. Control sections were spat upon to digest any glycogen on the section previous to staining. It was found that cartilage cells in the neighbourhood of the epiphysis store glycogen in direct proportion to their age. This is true not only of the cartilage cells arranged in columns at the epiphysial line but also of cartilage cells in relation to primary and secondary centres of ossification. Thus the cartilage cell in an avascular area exhibits its vegetative characteristics in the manner of storing glycogen. The more senescent the cell the greater the storage of glycogen. The osteoblasts and highly vascularised bone contain no glycogen. It is suggested that the senescent or hypertrophic cartilage cells provide both the phosphatase enzyme and the glycogen; the latter on hydrolysis yields hexose-phosphoric esters which under the action of the phosphatase and the calcium of the circulating body fluids lead to the deposition of an insoluble phosphate of calcium in the matrix.

In view of the atypical features attributed to Meckel's cartilage, sections of the lower jaw in a human embryo of 10 weeks were examined (Fig. 1). At this stage Meckel's cartilage consists of nothing but senescent cells heavily charged with glycogen. At the proximal end of the cartilage is a mass of osteogenic fibrous tissue in which early differentiation of the osteoblasts can be seen. The glycogen is distributed in the form of discrete fine dots of about 2μ in diameter. Adjoining this is seen the first

lamella of membrane bone with osteoblasts serially arranged along its free surfaces. Both the ground substance of the bone and the osteoblasts are devoid of glycogen.

Numerous examples are found in plant physiology and animal pathology of the manner in which new cells and tissues are able to live and multiply on the autolytic products of senescent and dying cells. This is a feature of new tissue in pathological inflammation no less than of the growing shoot in tubers such as the potato. It is suggested that the vegetative proliferating cartilage in the senescent stage provides at the site of future ossification both the store of glycogen for the production of the hexose moiety of the hexose-phosphoric ester and the active enzyme, the phosphatase of Robison. The circulating body fluids provide both the calcium and the phosphates which Kay has so frequently emphasised. The phosphatase leads to deposition of calcium salts in the matrix of the senescent cartilage. The osteoblast is a highly differentiated cell which appears with the irruption of those blood vessels that proceed to remove the virtually dead calcified cartilage by a process which has much in common with that seen in aseptic inflammation. The osteoblast is able to control the deposition and re-absorption of bone in this system, presenting many of the features of a reversible reaction. The osteoclast is a multicellular osteoblast which appears in response to an urgent demand for re-absorption of bone rather than deposition.

This preliminary note on the association of glycogen with phosphatase in the senescent cartilage cell for the purpose of bone formation may serve to focus attention on the manner in which biochemical conceptions are gradually destroying the hitherto satisfying but none the less unsatisfactory views of the mechanist in anatomy. It is interesting to note from the scant facts collated by Pryde[8] that in the unincubated egg phosphatase is absent (Kay) and also the hexose-phosphoric esters (Kay, Plimmer and Scott). Both substrate and enzyme reach a maximum by the twelfth day in the chick embryo and then steadily decrease. Glycogen is practically absent in the unincubated egg, appears about the second day and rapidly increases in parallel with the phosphatase and substrate. After the twelfth day the glycogen deposit in the liver of the chick increases rapidly. Creighton[9] in 1896 thought that "the cartilages which are destined to continue throughout life as cartilages have little or no glycogen in the fœtal period, but those which later will ossify have plenty and it usually appears in the spots which afterwards become ossification centres." Marchand[10] in 1885 said: "The increase in the size of the cartilage cells in the neighbourhood of the bone is due to the accumulation of glycogen or at least coincides with it." Needham[11] in his admirable compendium on "Chemical Embryology" says: "Nobody now accepts Creighton's views and the attribution of any special embryological importance to glycogen is superfluous. While it may be useful to know the histological distribution of glycogen in the embryo, at present little physico-chemical meaning can be attached to most of this work." It is suggested that the work of Robison, Kay and Fell does provide a physico-chemical meaning for the distribution of glycogen in areas of future bone formation. Moreover, examination of the developing tooth in the embryo displays a gradual transition from concrete accumulation of glycogen in the epithelium of the primitive dental furrow, to discrete particles of glycogen in the dentine germ and absence of glycogen in the fully differentiated ameloblast of the enamel organ. The 'vegetative' characteristics of cartilage and the rôle of vitamin D in promoting calcification therein have been emphasised repeatedly by me[12]. The association of glycogen, phosphatase, phosphoric esters and vitamin D in this 'vegetative' cartilage provides a new and fundamental approach to the processes involved in diseases of bone, joints and teeth.

Vitamin C and Hexuronic Acid

IN connexion with experiments under the direction of Dr. L. J. Harris[1] on the rôle of the suprarenal gland in vitamin C metabolism, we have investigated the silver nitrate staining capacity of glands taken from normal and scorbutic animals. It will be recalled that long before the identity of vitamin C with hexuronic acid was postulated[2,3], Szent-Györgyi[4] noticed the presence of a reducing substance (hexuronic acid) in the suprarenal cortex, which had the characteristic property of causing deep staining in the tissues when treated with dilute silver nitrate. It occurred to us that if the identity of vitamin C and hexuronic acid were genuine, suprarenals from scorbutic animals might react negatively, or less intensely in the staining test. In view of the unspecific character of the reagent and of the possible presence of other reducing substances, we were not sanguine that a clear-cut distinction from normal glands would be observed, but in actual fact the difference is unmistakable and dramatic. After staining for 15 minutes with 0·4 per cent silver nitrate solution, glands from normal guinea pigs were deeply blackened; glands from scorbutic guinea pigs were completely unaffected.

With the whole normal gland, staining was confined to the surface on account of failure of penetration by the reagent, but when the glands were cut the whole cross-section was blackened. No differentiation between cortex and medulla, similar to that observed by Szent-Györgyi in ox suprarenals,[4] and confirmed by ourselves, was noticed, but a final decision on this point must await detailed histological examination, since the relative sizes of the two zones show considerable variation in different species.

The above evidence lends further colour to the view that hexuronic acid and vitamin C are identical, or at least that their rôles are closely interrelated. Since, however, it is well known that the suprarenals become injured not only through vitamin C deficiency but also through vitamin B deficiency and simple starvation, caution may be necessary in accepting absence of staining capacity as a specific sign of avitaminosis C. The possibility of lack of

staining substance in the suprarenal from secondary causes must be kept in mind.

In preliminary experiments on suprarenals obtained from rats fed for prolonged periods on diets completely deficient in vitamin C, we have invariably observed positive silver nitrate reactions, even when through the simultaneous absence of vitamin A or the vitamin B complex the animals had reached a state of extreme emaciation. This finding is in good agreement with the current view that the rat is capable of synthesising vitamin C.

Calculation of the Reflectivities of Sulphide Ore Minerals

THE practical difficulties of the direct determination of the indices of refraction and absorption of the opaque ore minerals have resulted in little work in this direction being accomplished. The progress of ore microscopy, however, has established the measurement of the reflectivity for (nominally) vertically incident light, whether by visual photometry as developed by Berek[1] and Schneiderhöhn, or by a photoelectric ocular as developed by Orcel[2], as a routine process in the determination of these minerals. The figures obtained present evidence of certain regular relationships. Thus, amongst the simple sulphides, selenides and tellurides a general increase of reflectivity with increasing atomic number can be traced in such series as ZnS–CdS–HgS or PbS–PbSe–PbTe.

Amongst the more complex sulphantimonites and sulpharsenites, such as the series $x\mathrm{PbS}.y\mathrm{Sb_2S_3}$ or the Binn valley minerals $x\mathrm{PbS}.y\mathrm{As_2S_3}$, the relationships are less simple. To a first approximation, however, many of these minerals can be treated as transparent in small thicknesses, still relatively great compared with the wave-length of the light employed[3]. With this assumption an approximate refractive index n may be calculated from Fresnel's relationship

$$n = \frac{1+\sqrt{R}}{1-\sqrt{R}}$$

The value of n thus obtained is used to derive from the Lorenz-Lorentz equation

$$MR = \frac{M}{d}\,\frac{n^2-1}{n^2+2}$$

the molecular refractivity MR (usually, unfortunately, denoted by the same symbol R as is now universally adopted to denote the reflectivity). For anisotropic crystals for which R_a, R_β and R_γ are known, the value $\bar{n} = \sqrt[3]{n_a.n_\beta.n_\gamma}$ is used[4] in calculating MR. If this is done for the simple sulphides, selenides and tellurides, MR values are obtained which have the same additive relationships as the usual molecular refractivities calculated for transparent salts. Of forty-five complex opaque minerals chosen at random, the MR values calculated direct from the measured reflectivities (Schneiderhöhn-Ramdohr[5], and my own measurements with a photoelectric ocular), and those computed from the MR values of the constituent molecules showed a significant difference in only a single instance, that of klaprothite (klaprotholite), $3\mathrm{Cu_2S}.2\mathrm{Bi_2S_3}$; it may be suggested with some confidence that the value for d quoted in the literature and based on an early determination by Petersen should read, not 4·6, but 6·4, the value obtained by calculating backwards from the MR value. (I have not yet been able to examine a pure specimen of the natural mineral, but the crystalline mass obtained by the Sommerlad method[6] from the fusion of the constituents gave a value for d of 6·3.) These calculations therefore appear to be of interest from several points of view.

Electric Charges on Rain Drops

DURING the last year we have maintained in continuous action an apparatus for recording the electric charge on individual drops of rain. A drop of rain in order to have access into the insulated receiver has first to pass through a fixed but adjustable cylindrical opening of average diameter 1·4 cm. and then through a second opening of diameter 2·4 cm. at the periphery of a rotating disc. Both openings are provided with trap arrangements so that a drop striking the sides is caught and led away. The period of rotation of the disc is so adjusted that with moderate intensity of rain a second drop may not enter into the receiver until the charge of the first has been recorded and the system earthed by an automatic device. A glass manometer of very fine bore is attached to the receiver and keeps a record of the size and number of drops.

For recording the charge given to the receiver by a drop of rain, a Wilson tilt electroscope is used very nearly at its maximum sensitiveness, and the movement of the gold leaf is photographed by allowing light from a point source (a 'Pathé-Baby' projector lamp) to pass through a minute slit and a short focus lens and fall transversely as a narrow beam of about half the breadth of the leaf over a fine pin-hole made at its lower end, which is twisted at right angles to its plane. The transmitted light through the hole gives a magnified image of its displacement on a quickly moving photographic paper. All necessary precautions were taken to avoid the influence of the field of the earth and any artificial field on the drops.

This method of recording is of particular interest in view of the fact that the Wilson tilt electroscope has not to our knowledge been used in the past as a recording instrument. Simultaneously with the above apparatus, a Simpson apparatus giving the charge of rain collected every two minutes was kept in action.

An analysis of the records shows that both positively and negatively charged drops are present in the rain received from any part of the cloud. When the rain received during any interval is positively

or negatively charged as a whole, there is an excess of positively or negatively charged drops. The following table gives the charge per drop based on the measurement of about two thousand drops. In making the tabulations all drops were neglected the charge of which was less than 0·06 e.s.u.

	Charge per drop (e.s.u.)					
	Positively charged drops.			Negatively charged drops.		
	Mean	Absolute max.	Mean max.	Mean	Absolute max.	Mean max.
Non-thunderstorm rain	0·64	1·95	1·23	0·67	2·41	1·24
Thunderstorm rain	0·69	2·44	1·82	0·73	3·74	2·26

A detailed analysis of the observations with discussion will be given in our forthcoming memoir on the subject.

Diamagnetism of Thin Films of Bismuth

AT Prof. W. Gerlach's suggestion I have recently investigated the behaviour of the magnetic susceptibility of bismuth when measured in the form of thin films. A modified form of the Faraday method was employed, the measuring system consisting of a flat cross with four equal arms about 15 mm. long and 5 mm. wide, the arms being set at about 90° to one another. This system was constructed of glass about 0·1 mm. thick. A fine glass wire through the centre of the cross and perpendicular to its plane carried a small galvanometer mirror; the system was suspended from a torsion head by means of a fine quartz fibre and was thus free to turn about the glass wire as axis. The cross hung in an inhomogeneous, but symmetrical, magnetic field formed by two 60° wedge-shaped pole pieces such that each pole piece occupied the space between two adjacent arms of the cross. The plane of the cross was horizontal and parallel to the lines of force, the centre of the cross and field system being coincident. The gap between the pole pieces was about 10 mm. In the magnetic field the cross would take up a very definite position of equilibrium and this point was made the zero point of the system when no field was acting. A film of bismuth was now deposited on one long arm of the cross (that is, about 30 mm. long) thus upsetting the equilibrium and causing the system to be deflected, which in turn was brought back to its initial zero position by means of the torsion head, the angle of deflection being determined by a telescope and scale in the usual way.

The films were produced by evaporation from an electric furnace such that they were about the same size as one long arm of the cross, that is, about 30 mm. × 5 mm., and of very uniform thickness. The deposition of the films and measurements were made in vacuum; it was impossible however to outgas the cross system. The procedure was first to deposit a very thin sensitising film, the magnetic properties of which were negligible, in order to have a more or less definite surface on which to deposit the thicker films. A film was now deposited and the deflection measured; over this was now deposited a very much thicker film and the deflection again measured, always from the initial zero position in the same field. Of course an intermediate film between the thick and the thin one could be deposited and measured if desired. If θ, K and d refer respectively to deflection, volume susceptibility and thickness of a given film, since the field remains the same for two or more given measurements,

$$\theta \propto Kd$$

$$\text{or} \quad \frac{K_2}{K_1} = \frac{\theta_2}{\theta_1} \cdot \frac{d_1}{d_1 + d_2}$$

Hence in order to compare the susceptibility of a thin and a thick film we must know the ratio of d_1 to d_2. By means of a shutter in the apparatus the time of deposition of the films could be accurately controlled. Both films are deposited under the same conditions of temperature and pressure in the apparatus. In order to give absolute values the thickness of the final film ($d_1 + d_2$) was determined in the usual way by weighing. From the times of deposition the ratio d_1 to d_2 is known and d_1 and $d_1 + d_2$ are known absolutely. The susceptibility of the thin film is then known in terms of the thick one.

Lack of space prevents giving a detailed table of results but in some forty determinations ranging in film thickness from 0·2 μ to 15 μ no variation of the susceptibility could be found. Certainly the fluctuations between readings is rather large (some 12 per cent) but these readings are all grouped around a mean value which is quite constant. I believe we can draw the conclusion that, in the given range, the susceptibility of bismuth remains constant.

A considerable amount of work on the susceptibility of colloidal powder of bismuth and other metals (Sb, Ag, Au) has been done by Vaidyanathan,[1] Rao[2] and others. These authors find that with decreasing particle size the diamagnetic susceptibility decreases and have advanced the hypothesis that the susceptibility becomes a function of the particle size when this is less than 10 μ. While Mathur and Varma[3] in a careful series of tests have shown that a large part of this decrease in bismuth is due to oxidation, Rao[2] still finds a change when the oxide is removed as completely as possible. If, however, diamagnetism actually depends on particle size, we should expect the experiment described here to show it, since we know that a thin film is composed of small crystallites the size of which decreases as the film thickness is decreased.

I would suggest that the hypothesis recently advanced by Seemann and Kussmann[4] to explain the effect of cold work on the susceptibility of metals might also account for the effect observed in colloidal powder. The process of mechanical colloidalisation (that is, grinding) could be looked upon as cold working, which sets free ferromagnetic impurities in the metal giving rise to a decrease in diamagnetism. Melting the colloidal powder (as Rao has done) would again render the impurity inactive giving rise to an increase in diamagnetism as observed. It might be possible to make a direct check on this point by measuring the susceptibility of each powder at various field strengths, since as the particle size decreases the susceptibility should show more and more variation with the field.

Velocities of Emission of α-Particles

THE relative velocities of the α-particles from thorium X, thoron, thorium A, thorium C, thorium C′ and radium C′ have been measured by the direct magnetic deflection method using a permanent magnet[1] giving a field of about 5,000 gauss. The deflections were measured with a microphotometer, and by carefully investigating possible sources of error such as loss of velocity by absorption at the source, non-uniformity of the magnetic field, and the effect of any movements of the photographic emulsion during development, it has been possible to obtain a considerable improvement in the accuracy of measurement of α-ray relative velocities.

The results for the relative velocities are shown below; the probable error is 1 in 20,000. The absolute velocities are deduced from the value $1 \cdot 922 \times 10^9$ cm. sec.$^{-1}$ for radium C′ [2].

	Relative Velocity	Absolute Velocity
Radium C′ ..	1·00000	$1 \cdot 922 \times 10^9$ cm. sec.$^{-1}$
Thorium X ..	0·86042	$1 \cdot 653_9$
Thoron ..	0·90464	$1 \cdot 738_9$
Thorium A ..	0·93935	$1 \cdot 805_4$
Thorium C ..	0·88811	$1 \cdot 707_0$
Thorium C′ ..	1·06872	$2 \cdot 054_1$

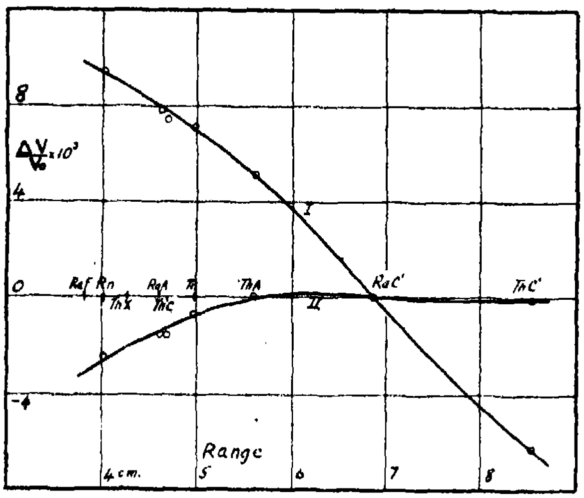

FIG. 1.—The relation between range and velocity of α-particles. Curve I, deviations from the Geiger relation $V^3 = kR$; Curve II, deviations from $V^{3 \cdot 36} = kR$.

The complexity of thorium C discovered by Rosenblum produced a slight broadening of the line but no evidence of complexity was found in the other groups. The velocity for thorium C corresponds to the weighted mean of the two main components.

The relative velocities of the α-particles from radium A, radon, and radium C′ are also being measured and the following preliminary results have been obtained:

	Velocity relative to Radium C′	Absolute Velocity
Radon	$0 \cdot 8455 \pm 0 \cdot 0003$	$1 \cdot 625 \times 10^9$ cm. sec.$^{-1}$
Radium A	$0 \cdot 8839 \pm 0 \cdot 0002$	1·699

From the velocity ratios obtained in this work and the range measurements of Lewis and Wynn-Williams[3] a new correction curve (Fig. 1, curve 1) to the Geiger relation, $V^3 = k R$, has been calculated from the equation

$$\Delta V/V_0 = V/V_0 - (R/R_0)^{\frac{1}{3}}$$

used by Rutherford, Ward and Lewis[4]. V_0 and R_0 are the velocity and range of radium C′.

It is found that the equation $V^{3 \cdot 36} = k R$ accurately expresses the relation between velocity and range above a range of 5 cm. The deviations from this relation calculated similarly are shown by curve II.

From these curves the velocities relative to radium C′ may be calculated with a maximum error of 0·0004, for other groups of α-particles the ranges of which have been measured by Lewis and Wynn-Williams.

	Velocity relative to Radium C′	Absolute Velocity
Actinon (short)	0·9179	$1 \cdot 764 \times 10^9$ cm. sec.$^{-1}$
Actinon (long)	0·9420	1·811
Actinium A	0·9795	1·883
Actinium C (short)	0·9034	1·736
Actinium C (long)	0·9282	1·784
Actinium C′	0·9841	1·891
Polonium	0·8310	1·597

There are systematic differences between the results given above for thorium C (mean), thorium C′ and radium A, and those obtained earlier by Rosenblum[5] in the course of his experiments on the fine structure of α-ray spectra using the large electromagnet of the Paris Academy of Sciences. Recently, however, Rosenblum and Dupouy[2] have measured the velocities of seven groups after having made a fresh exploration of the field of the magnet. The results agree to well within the limit of error, 0·5 to 1 in 1,000, with those reported here.

Productivity of the Fisheries North and South of the Suez Canal

THE work of the great oceanographical expeditions, and the experience of the fisheries administrations in the different countries, have alike gone to show that living things are more abundant in temperate and polar seas, than in those of the tropics and subtropics.

It is a little surprising, therefore, that the fisheries of the Gulf of Suez should have the reputation of being more productive than those of the Mediterranean coast of Egypt; for, though I have shown elsewhere[1] that the Port Said end of the Suez Canal may be the hotter, this is only so for six months of the year, and even then must be regarded as a local effect, the main water masses of the northern Red Sea being always hotter and salter than the eastern Mediterranean.

That the Gulf of Suez fishery is indeed more productive, is well shown by the evidence of the Egyptian fishery statistics concerning the trawl fishery, where the mean catch in kilograms per net per day's fishing at Alexandria and Suez for the last ten years, and at Port Said for the last nine are: Alexandria, 115; Port Said, 131; Suez, 232.

In the long line fishery, a motor ketch, working in the summer of 1930 from Alexandria, and in the summer of 1931 from Suez, gave a greater yield per basket of lines at Suez, compared with Alexandria. Nevertheless, as much of the Suez catch was made up of dogfish, sharks and rays, the catch at Alexandria was sixteen times as valuable. Similarly in the trawl fishery, though elasmobranchs form only a small

part of the catch at Suez, the Red Sea fish are not esteemed as much as those of the Mediterranean, and the Alexandria catch is more valuable.

Finally, and in addition to the evidence of the commercial catch, my own observations (based on the change in hydrogen ion concentration on storing water samples, *loc. cit.*) and those of Natterer[2] show that there is more organic matter in the water of the southern than in the northern part of the Suez Canal.

The explanation of this anomaly seems to me to be a tidal one. At Suez there is a considerable ebb and flood, which is absent at Port Said. This tidal scour must cause a thorough vertical and horizontal mixing of the water mass in the head of the Gulf of Suez and the southern end of the Suez Canal. It would replenish with basic food materials areas that might otherwise have become exhausted as a result of the synthetic activities of marine algæ. On the other hand, and particularly so between February and August, when the Nile out-flow is dammed, the water of the Mediterranean coast of Egypt must be relatively stagnant, and, for such mixing as there is, will depend mainly upon the strength and direction of the wind in the coastal area. Under these conditions, one can quite easily see that in long periods of calm weather the basic food materials necessary for algal growth would be used up, and in the absence of further supplies being circulated, this growth would cease. It is, of course, upon this algal and other plant growth that the yield of the fishery ultimately depends.

Cystine and Wool Production

ATTENTION continues to be directed to the difficulty of accounting for the manner in which sheep on pastures secure the cystine necessary for wool growth. In a recent communication to NATURE,[1] Rimington and Bekker conclude that the amount of cystine consumed in the grass fails to account for the amount present in the fleece and formulate an alternative hypothesis that "The intestinal flora and fauna .... are almost certainly able to synthesise cystine from inorganic sulphur and it is conceivable that the population of the sheep's intestine, by continual increase, is transforming sulphates into cystine, built into their own protoplasm, with a high grade of efficiency. As bacteria die, their cell protoplasm autolyses, again setting free the sulphur, now in the form of cystine, which is readily available to the sheep."

Although this hypothesis is attractive, the evidence against it is considerable. Various Continental and American workers have noted that the bacterial flora of the intestine readily decompose sulphur-containing bodies and even elementary sulphur to hydrogen sulphide, ethyl mercaptan and similar compounds which, *on absorption*, are very rapidly oxidised by the blood stream and excreted as urinary sulphates. The possibility of the transformation of inorganic sulphur into cystine by such means has not been demonstrated, however. Recently, we have also studied the activity of cellulose-splitting bacteria isolated from the contents of the sheep's rumen by continuous sub-culturing in a medium containing ammonium sulphate as a source of nitrogen and sulphur. Although there was a pronounced decrease in sulphate sulphur and the formation of hydrogen sulphide, there was no evidence of the formation of cystine or any similar sulphur compound. Fraser and Roberts[2] have made the suggestion that "cystine is formed during keratinisation, and that cystine synthesis is a function of the wool follicle itself. The amount of cystine produced in a fleece would then depend upon the number and activity of the wool follicles, and not upon the cystine content of the food or the bacterial population of the intestines."

It is of the utmost importance, from the point of view of pastoral industry, that the whole problem should be brought into its proper perspective. The recent work of Evans[3] has shown that cultivated pasture, under English conditions at any rate, contains about 0·1 per cent of cystine on the basis of dry matter (*not* 0·01 per cent as is accepted as the average figure by Rimington and Bekker). Considering the case cited by these investigators, and assuming that a fully-grown sheep is able to consume daily an amount of pasturage containing 4 lb. of dry matter, it follows that the necessary 0·78 lb. of cystine in a 12 lb. fleece would be secured from the pasturage during a grazing period of 195 days. Even on the assumption that only 50 per cent of the cystine in the grass is actually retained in the animal for purposes of wool-protein synthesis, it is clear that a sheep would consume per annum roughly all the cystine necessary for the growth of a 12 lb. fleece. If, however, the average wool production per head of the sheep population in Great Britain be taken at the much lower official estimate of 5–6 lb.,[4] then the argument becomes even more convincing.

We are led to the belief, therefore, that under English conditions, there is no difficulty in accounting for wool production in sheep subsisting wholly on pasturage. The cystine content of the herbage, although apparently low, is adequate for this purpose. The previous interpretation of the figure obtained for the cystine content of grass as indicating the presence in the herbage of a cystine precursor becomes therefore superfluous.

Radiation and Enzyme Activity

A SYSTEMATIC study of metabolic radiation by a modified photographic method in this laboratory (to be published at a later date) has revealed the following facts: (1) Radiation is a general function of normal organic metabolism, being exhibited by blood, milk, eggs, brain, bone-marrow, lung, the pituitary (anterior and posterior lobe) and the parathyroid gland, urine, roe of plaice, yeast, Demerara sugar, honey, etc. (2) Radiation fades with the lowering and re-appears with the raising of temperature; it is inhibited at −5° to −10°, destroyed by heating at 98°–100° for two hours, inhibited by carbon monoxide in the dark but regenerated in sunlight, and destroyed by hydrogen peroxide, potassium permanganate and potassium cyanide. (3) Pure cholesterol, vitamins (C and D), sucrose, hormones and alkaloids as such are void of radiation.

Comparing the occurrence of radiation and the influences controlling it with the distribution and characteristics of respiratory enzymes, we have no difficulty in recognising radiation as an inseparable part of normal enzymatic activity (oxidase, dehydrogenase).

This deduction links two hitherto unrelated lines of research on malignant growth, namely, (*a*) Warburg's work on abnormal glycolysis by restricted activity of respiratory enzymes, and (*b*) Gesenius's investigation on inhibited radiation in relation to disease.

Excluding parasitic inhibition (syphilis, tuberculosis) and passivity caused by suppressed intake of oxygen (pernicious anæmia), the depletion of respiratory enzymes in cancerous cases may be due to enzyme starvation, for which our diet and culinary methods are mainly responsible. To restore normal metabolism in all its phases we should require the introduction of a cellular system capable of regulating glycolysis, the vitamin and hormone equilibrium, to be non-toxic and able to function under partly anærobic conditions. Yeast, especially commercial baker's yeast, in an enzyme-bearing medium (unrefined sugar, honey, etc.) which is respiratorily much more virile than any pure culture, should provide such an enzymatic association.

Local inductive and contact influences (rays, tar, etc.), affecting respiratory enzymes, become, if protracted, carcinogenic.

Liesegang Rings

DR. HEDGES is to be congratulated on his book on "Liesegang Rings", which gives for the first time a comprehensive survey of the subject together with a most extensive bibliography. It will be a valuable work. His description of my theory is adequate, except that he is incorrect in stating that it does not account completely for all the facts. The example quoted against it is a beautiful confirmation. The formation of zones of precipitated sodium chloride is due to the oppositely diffusing solutions of hydrochloric acid and sodium chloride being constrained by the capillary tube to pass near the deposited salt. This demonstrates the essential part played by the precipitate in removing the solute from the solution in its neighbourhood.

This experiment is not the first case of so-called rhythmic precipitation without chemical reaction. In 1921[1] I described beautiful bands of tiny gelatin particles suspended in water, which were formed by diffusing alcohol into dilute solutions of gelatin. Further, my adsorption theory explains the formation of banded structures by crystallisation.[2]

Dr. Hedges proposes an alternative theory that the phenomenon requires "(1) a critical condition, which has to be reached before crystallisation, precipitation, coagulation, condensation, or other change involved in the formation of the periodic structure takes place, and (2) mobilisation of the material which can occur during the delay caused by the first condition. In this way material is moved from the zone which eventually become the spaces to those which eventually become the rings." This attempt at generalisation is too indefinite as a working hypothesis. The majority of systems included would give no periodic structures. It does not indicate the part played by the precipitate, or specify that it must be held in place. Even if the statement is made more definite by specifying supersaturation as the critical condition and diffusion as the means of mobilisation, only a very small proportion of the many systems that would conform to these conditions would produce good banded precipitates. The theory is incapable of explaining the facts in detail as my adsorption theory does.

Carbon-Oxygen Linkage in the Metal Carbonyls

DADIEU and Kohlrausch[1] have shown that the $>C=O$ group in aldehydes, ketones and esters, is associated with a Raman displacement of 1,500–1,700 cm.$^{-1}$; Rasetti[2] found for carbon monoxide a shift of 2,155 cm.$^{-1}$, in satisfactory agreement with the structure $\overset{-}{C}\equiv\overset{+}{O}$. Observation of the Raman effect in the metal carbonyls should therefore discriminate between a co-ordinated structure[3], and any cyclic structure embodying $>C=O$ groupings.

Through the kindness of Prof. A. Fowler, I have been able to photograph the Raman spectrum of nickel carbonyl, and to find a strong line corresponding with a displacement of 2,038 cm.$^{-1}$, together with a number of diffuse lines of displacements up to 450 cm.$^{-1}$. Since the performance of this preliminary experiment, Dadieu and Schneider[4] have examined the Raman spectrum in detail, and found shifts of 2,125 and 2,039 cm.$^{-1}$, corresponding to the carbon-oxygen linkage, together with lines at 595, 456, 379 and 80 cm.$^{-1}$ which have been attributed to the fundamental frequencies of a tetrahedral molecule.

The Raman effect thus affords decisive evidence that the carbon monoxide is present in the molecules of the metal carbonyls as such, the difference between the value 2,155 cm.$^{-1}$ found for carbon monoxide itself, and the doublet 2,125 and 2,039 cm.$^{-1}$ found in the case of nickel carbonyl being attributable to the modification in the forces operative in the carbon-oxygen linkage brought about by the co-ordination of the carbon monoxide to the metal, and the consequent redistribution of polarities.

It is important to note that this evidence, as also that derived from measurement of the dipole moment[5], is in full accord with the chemical properties of the carbonyls, in particular the replaceability of the carbon monoxide by amines (cf. the formation of the compound $Ni(CO)_2.C_{10}H_8N_2$ and analogous iron and cobalt compounds[6]). The convergence of evidence may therefore be taken as establishing beyond doubt a structure of the type indicated above.

Research Items

Dried Head from New Guinea.—Mr. H. G. Beazley figures and describes in *Man* for December one of the rare dried heads of the Marind-anim (Tugeri) peoples of Dutch New Guinea. Two methods of preserving the head are known from the various districts of New Guinea. In addition to the 'preserved' head method, is that in which a reconstruction of clay overlies the cranium. In the specimen described here both methods are followed. While the original skin still covers the features, the posterior portion is entirely constructed of clay. The Tugeri to-day are an inland people; but they make periodical raids down river in their canoes on the peoples who inhabit scattered islands at the river mouth. It is possible that originally they were a coastal people, who were driven inland by later arrivals. Their social organisation would seem to require a steady stream of captives for the supply of these reconstructed heads, which are obtained from the captives brought back to the Tugeri villages. The prisoners' legs are broken to prevent their escape and their death takes place only at the feasts that are held on the return of the raiders. The object of the raids is to secure the souls of the victims, and immediately before they are killed they are made to cry out by ill-treatment. Whatever cry is uttered is accepted as the name of the spirit. The word is treasured and the influence of the spirit, of which it is the name, will guard and benefit the captor. An outstanding feature of this type of preserved head is the fibre 'wig', which is added owing to the fact that most of the coast peoples have short hair. Lengths of fibre are close woven at their base to form a close-fitting cap which is attached to the scalp.

Bari Initiation.—Fr. L. M. Spagnolo contributes notes on the initiation of young men and girls among the Bari tribe of the Sudan to *Africa* (vol. 5, No. 4). Initiation of the youths was, in the days before the Bari were affected by white civilisation, one of the links between the chief and his people. When his son had reached the age of entering the ranks of the warriors, the chief would present him with a bull and bid him summon all the youths of his age-class, who henceforth would form his bodyguard. They assembled on an appointed day, a bull was killed with the usual ceremonies, and much beer drunk. The young chief of the class then announced the name by which his class would be known, this usually expressing some attribute such as courage, strength and the like. The name was chanted in all tribal songs sung at marriages, funerals and on similar occasions, and was used as a battle cry. The class formed a society with bonds which only death could sever. The custom is now falling into disuse. The initiation of young girls fell into five stages, which entailed cicatrisation at certain ages, beginning at about fifteen. In the fourth stage the initiates had the lower canines and incisors removed to mark the passage from girlhood to married status. No girl could marry unless she had undergone this stage of the ritual, and failure to comply caused infecundity. The neophytes lived in seclusion and the operation was carried out by a skilled operator with an iron instrument, sometimes reinforced by a stone. The period of seclusion was passed in singing, dancing, and in the preparation of a number of ceremonial objects. Certain taboos had to be observed. At the close of the period—about three months—suitors presented gifts to the girls and to the members of their family. The last tattooing takes place about two years after the extraction of the teeth, that is, when the girls are something over twenty years of age. Age classes, five for each sex, determine the joint of the fat ox to which participants are entitled at ceremonial feasts.

Contraception and Fertility in Women.—"Contraception and Fertility in 2,000 Women" by Raymond Pearl (*Human Biology*, vol. 4, September, 1932), is a preliminary report on the first 2,000 cases collected in an investigation of the prevalence and effectiveness of the use of contraceptives. The data are collected by physicians attending women who are undergoing parturition in the obstetric clinics of 38 large hospitals in the United States. As Prof. Pearl points out, selection is an important factor in the inquiry and the data cannot be regarded as a sample of the general population because there were no women from rural areas and all the women had been delivered of a baby in hospital. No data were collected from Roman Catholic hospitals. The cases were almost entirely from the lower economic and social levels; 70 per cent were white women and 30 per cent negroes. The average number of pregnancies was 2·68 for white women and 2·89 for negroes. It would appear from this sample of women that the practice of contraception is far less prevalent than is commonly supposed, for only about 36 per cent of white women and 15 per cent of negroes had made some attempt to prevent conception. The different methods of contraception used were such that the white men alone assumed 48·7 per cent of the responsibility of family limitation, the white women alone 49·3 per cent and the couples conjointly 2 per cent. Among the negroes, family limitation was practised more by the women; the males alone assumed only 33·1 per cent of the total responsibility, the women 64 per cent and the couples together 2·9 per cent. A new method is described for calculating person-years of exposure to risk of pregnancy. No definite conclusions are attempted in this preliminary study. There is some reason to think, though it is not yet demonstrated, that women who practise contraception are innately more fertile than women who do not.

Distribution of Bugs of the family Peloridiidæ.—The remarkable hemipterous family Peloridiidæ has formed the subject of a number of speculative and controversial papers during the last decade. The interest which these insects arouse is due partly to their excessive rarity but more particularly to their extremely puzzling relationships. Indeed, it proved necessary to establish a special series within the suborder Homoptera for this one family with its three genera, each with only one species. Practically nothing was known of the habits of these bugs and it is only recently that Hacker has published (*Queensland Agri. J.*, vol. 37, 1932) some authentic observations on the ecology of *Hemiodœcus veitchi*, which proved to be a forest insect associated with the antarctic beeches of the genus *Nothofagus*. On the basis of this discovery, W. E. China (*Ann. Mag. Nat. Hist.*, vol. 10, October, 1932) has analysed the distribution of other members of the family. One of

them, *Peloridium hammoniorum*, is known from the vicinity of the Straits of Magellan, where several species of *Nothofagus* occur; another, the New Zealand *Xenophyes cascus*, has been found in a locality where several species of *Notofagus* are known to occur; the habitat of the Tasmanian *Hemiodœcus leai* remains unknown, but a species of *Nothofagus* grows there. The existence of a species of *Nothofagus* in the McPherson Range in Queensland, together with the occurrence there of a peloridiid, suggests that the range in question can be regarded as a relic island of the ancient antarctic flora and fauna, comparable to the European Alps with their isolated arctic species of plants and animals.

Respiratory Organs of Isopod Crustacea.—Mr. Ernest E. Unwin has described the respiratory organs and their modifications found among various genera of terrestrial Isopoda forming the group Oniscoidea or wood-lice (*Papers and Proceedings, Roy. Soc. Tasmania*, 1931, pp. 37–104). These Crustacea inhabit very diverse situations, some requiring wet conditions while others live amid comparative dryness. In this connexion there are correlated modifications in the organs of respiration. In all cases the exopodites and endopodites of the first five pairs of abdominal appendages are respiratory in function. The endopodites are uniformly thick-walled, somewhat flattened sacs filled with blood. Their surfaces are coated with a film of water and the author concludes that they are capable of absorbing oxygen through the medium of this moisture layer. The exopodites, on the other hand, present greater structural diversity. In *Oniscus* and *Philoscia* there is a special thin extension of the outer border of the exopodites forming small lung chambers. In such cases the blood follows through radial passages in the thin-walled plate and the air bathes the surface of the special organ. In *Porcellio*, *Armadillidium* and other genera the outer wall of the exopodite is invaginated to form a branching system of very thin-walled air tubes. The blood within the cavity of the exopodite bathes the surfaces of the air tubes. The second method of respiration is comparable with the tracheal respiration of Insecta but the wood-lice are handicapped by the small size of the organs concerned and their inability to do without endopodites. These facts appear to have limited the range of wood-lice, since they have to seek situations favourable for both types of breathing.

Pedigree Strains of Herbage.—The results of the comprehensive trials with pedigree strains of herbage, carried out at the Welsh Plant Breeding Station, Aberystwyth, during the seasons 1926–1931, have been published from the Station as Bulletin No. 13, Series H. The evidence obtained shows how far we are at present from being in a position to lay down truly scientific rules for the maximum exploitation of grasses and clovers, but although much critical field experimentation is still needed before our knowledge can be translated into terms of practical grassland management, the information already obtained allows of certain important generalisations being made. For example, no two species or strains of grass react similarly to factors (such as grazing or nitrogenous manuring) which influence seasonal productivity, palatability or persistency, and as a means of securing the right type of herbage at the right season, a simplification of the botanical personnel of the swards in conjunction with a rotational system of grazing is suggested. As regards the live weight increase of sheep fed on the different pastures, the outstanding result is the exceptionally high feeding value of wild white clover. An increase in live weight and carrying capacity of the sward was also obtained by the application of a nitrogenous manure, although this entailed a decrease in the percentage of clover present. Chemical analyses carried out to determine the effect of dressings of nitrogen on the composition of the individual grasses show that the nutritive value and palatability of a pasture can, to a considerable extent, be controlled by careful selection of the most suitable species, coupled with judicious management.

Virus Diseases of the Peach.—Three virus diseases of the peach in Michigan are described by D. Cation, in Circular Bulletin No. 146 of the Michigan State College, Agriculture Experiment Station (pp. 1–11, 1932). The diseases known as 'peach yellows' and 'little peach' are well known in peach-growing districts, but the trouble known as 'red suture' is of more recent occurrence. The foliage of infected plants becomes bronze in colour, giving the tree an unhealthy appearance, and the fruits bear a distinct red ridge along the suture. The malady is transmitted by grafting and is, in all probability, a virus disease. The bulletin under review deals with the symptoms and control of all three diseases.

Crystallisation of Pyroxenes.—An important contribution to the current discussion as to the course of crystallisation of pyroxenes from rock magmas is made by S. Tsuboi (*Jap. J. Geol. Geog.*, 10, 67–82; 1932). Whereas Barth found that in the basaltic rocks of the Pacific, South Africa, India and Cape Verde the porphyritic pyroxenes are diopsidic, while those of the ground-mass are pigeonitic, Tsuboi finds that in the majority of Japanese andesitic and basaltic rocks both monoclinic and rhombic pyroxenes occur as phenocrysts. It is suggested that in the intratelluric stage crystallisation may begin with either type of pyroxene according as the composition of the original magma lies in the field of monoclinic or rhombic pyroxenes. Only a limited degree of miscibility prevails in this stage. In the effusive stage, however, there is no limit to the miscibility of the pyroxenes, and in the residual liquid that remains both components crystallise in a single pigeonite phase. This inference corresponds with the results obtained by Bowen in his experiments with artificial pyroxenes under pressure conditions like those of lava flows. The variation of the course of crystallisation with pressure changes as well as with changes of composition in the residual liquids makes it possible to understand more clearly some of the apparent discrepancies between fact and theory in the very complicated history of pyroxene crystallisation.

After-Shocks of the Hawke's Bay Earthquake of February 3, 1931.—A brief, but valuable, summary of the New Zealand earthquakes of 1931 is given by Dr. C. E. Adams and Dr. J. Henderson in Bulletin No. 84 of the Dominion Observatory, Wellington, N.Z. The outstanding feature of the year was the destructive Hawke's Bay earthquake of February 3, the epicentre of which lay on the coast-line of Hawke's Bay 5–15 miles north of Napier, and the focus at a depth of 10–15 miles. The frequency of the after-shocks, at first great, declined rapidly. During the rest of February 595 were recorded, but the number fell to 79 in March and 12 in December. Of the total number, 17 were of intensity 6 (Rossi-Forel scale)

or higher. A semi-destructive shock (intensity 8) occurred on February 13, with its epicentre close to the middle point of the chord joining the extreme points of the Bay. The positions of the epicentres of forty of the principal after-shocks of 1931 have been determined and are represented on the map accompanying the paper. It is remarkable how many of these epicentres lie along or close to the chord of the Bay and its continuations, that to the north passing close to Gisborne and therefore to the epicentre of the important after-shock of September 16, 1932 (NATURE, 130, 468; 1932).

Electrochemical Theory of Organic Reactions.—Two lectures by Prof. R. Robinson, published by the Institute of Chemistry, give a very convenient review of this subject, with a bibliography. Prof. Robinson dealt with the applications of the modern electronic theory of valency to organic reactions, taking up various aspects of the problem. The general or inductive effect due to the disturbance in electron arrangement owing to the presence of groups is considered in relation to the strengths of acids and bases. Reagents may be classified into anionoid, or electron donating, and cationoid, or electron accepting, which groups include reducing and oxidising agents, respectively. Electromeric changes constitute a second type of electron displacement which appears in the simplest form in the course of the saturation of olefines or the additive reactions of carbonyl compounds. There is then a tendency for electrons in the double bond to break away from carbon and become attached to oxygen. Normally, such changes have a very restricted amplitude except in the course of reactions. All reactions of unsaturated substances are considered to be preceded by a degree of electromeric polarisation. A classification of conjugated electromeric systems into polyenoid C=C–C=C; hetero-enoid –N–C=C (with N written as a trivalent centre); cationoid C=C–C=O; neutralised systems O–C=O; dicationoid and dicatio-enoid (quinonoid) O=C–C=O and O=C–C=C–C=O; and dissociating systems, such as the carboxylic type, are discussed. Prof. Robinson then dealt with polar symbols for inductive, field and electromeric effects, with examples; anionoid reactivity of aromatic types; ordinary aromatic substitution, and cationoid reactivity of aromatic types. These lectures bring together a large amount of interesting material in a logical sequence and are a very useful contribution to modern chemical theory.

Astronomical Topics

Comet 1932 *n* (Dodwell-Forbes).—This comet, the magnitude of which is between 10 and 11, was found independently by Mr. G. F. Dodwell, the Government Astronomer at Adelaide, and by Mr. A. F. I. Forbes at Hermanus, Cape of Good Hope. It is Mr. Dodwell's first comet and Mr. Forbes's fourth. The following observations are from U.A.I. Circulars 409, 410, 411 and 413:

U.T. 1932	R.A. 1932·0	S.Decl. 1932·0	Place
Dec. $17^d\ 13^h\ 0{\cdot}0^m$	$23^h\ 2^m\ 23^s$	28° 48′ ″	Adelaide
18 17 58·7	23 6 50·9	27 53 0	Johannesburg
19 0 17·4	23 7 45·0	27 41 33	Harvard

The time of the first observation was telegraphed as 1^h; but that was in daylight, and comparison with the other positions leaves little doubt that 13^h is correct. The Harvard observation was by Dr. Whipple and Mr. Cunningham; they have deduced the following elliptical orbit from their own observations on December 19 (beginning), 19 (end), and 21; the interval is so short that great precision cannot be expected:—

$$
\begin{array}{ll}

,, 19	0 56 52	0 1

The comet is nearest to the earth about January 17: distance 0·9 of a unit.

The comet does not appear to be identical with any previously observed. If T is in 1932, it makes the tenth observed comet to pass perihelion in this year. This number was only exceeded once; there were eleven perihelia in 1925, and ten in 1898; these are the only years with double figures. The number of discoveries in 1932 was thirteen, which is the greatest on record; but one of these comets passed perihelion in 1931, and two others were not sufficiently observed to enable their orbits to be computed.

Work of the Naval Observatory, Washington.—Vol. 13 of the publications of this Observatory contains interesting details of the observations of three total solar eclipses. That of January 1925 was observed from an airship, which was too unsteady for delicate photography; nevertheless, some interesting pictures are given of the spectrum of the chromosphere and corona; the former was traceable to λ8800, the latter to λ7100. The eclipse of 1926 was observed in Sumatra; there are two beautiful reproductions of coronal photographs taken with the 65-ft. camera. Pictures on a smaller scale, taken with a cinematograph, show a good deal of detail in the outer corona; the reality of the features shown is checked by comparing different images.

The 65-ft. camera was taken to Iloilo (Philippine Islands) for the 1929 eclipse; also an 11-ft. camera. Pictures with both of these are reproduced. The report contains a vivid account of the eclipse seen from an aeroplane.

The Sproul Observatory sent an expedition to Sumatra in 1929: an hour elapsed between totalities at the two stations. Comparison of coronal details on the Sumatra and Iloilo plates shows systematic outward motion. The mean velocity from ten coronal markings was 3·8 km./sec.; since there must be some foreshortening, the true speed is greater.

The volume closes with a discussion of errors of the moon's longitude from 1866 to 1929, based on the results of many observatories, and compared with Brown's tables. The observed-minus-tabular longitude was 0″ in 1871, −3″ in 1893, 0″ in 1902, +8″ (maximum) in 1922, +6″ in 1928. The residuals after removing the great empirical term are also given.

The Modern Radio-Meteorograph

THE difficulties and uncertainties of securing measurements of upper-air temperature, pressure, etc., by means of the customary *ballon sonde* are already well known. Considerable value therefore is attached to methods which cause the recording meteorological instruments to operate a small radio transmitter carried with them by the ascending balloon and sending out some form of distinctive signal which can be received immediately on the ground and used to compile a record of the elements concerned.

What is believed to be the first kind of such radio-meteorograph was devised a few years ago by Prof. Moltchanoff, of Leningrad, records of temperature and pressure being obtained in several test ascents in January, 1930. Considerable modifications have since been made in the design. Humidity records have been included as well as those of temperature and pressure, while the method of radio control now

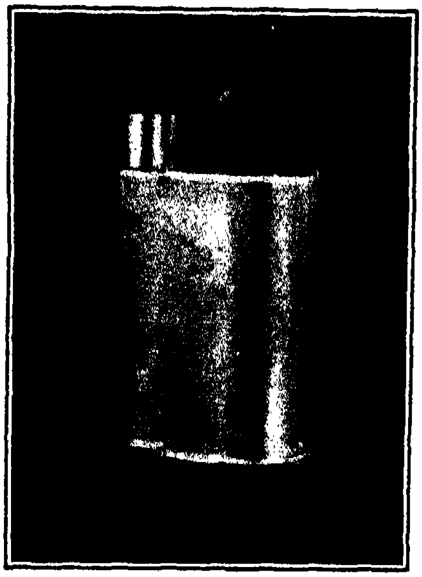

FIG. 1.

employed is such as to permit automatic recording by instruments of the rotating cylinder type such as are used for wireless picture reception.

The new pattern of Moltchanoff's radio-meteorograph is made by Askania-Werke of Berlin.

The apparatus consists essentially of a small short-wave radio transmitter (25-100 metres) located at the middle of a dipole antenna which trails below the balloon. The external appearance of the instrument is seen in Fig. 1. The disposition of the apparatus is shown in Fig. 2, which shows the wireless transmitter T and its small batteries B for filament heating and anode supply. The frequency of the transmitter is controlled by a quartz crystal in order to maintain constancy of frequency over the range of temperature encountered in practice. Special dry batteries have also been developed to withstand the lower temperatures, as difficulties were encountered with batteries of ordinary type. The batteries are additionally protected by thermal insulation in the course of their assembly into the transmitter.

The transmitter is of normal c.w. type and emits its signals under the control of a contact which makes or breaks its anode circuit in accordance with the elements to be signalled. The arrangement of this control is shown schematically in Fig. 3. A contact-arm A is rotated continuously by a clockwork drive. The three pointers of the appropriate measuring elements are arranged one above the other so that they move on a uniform circle, the top of each pointer making a fleeting contact with the brush of A in the course of its rotation. The brush also makes

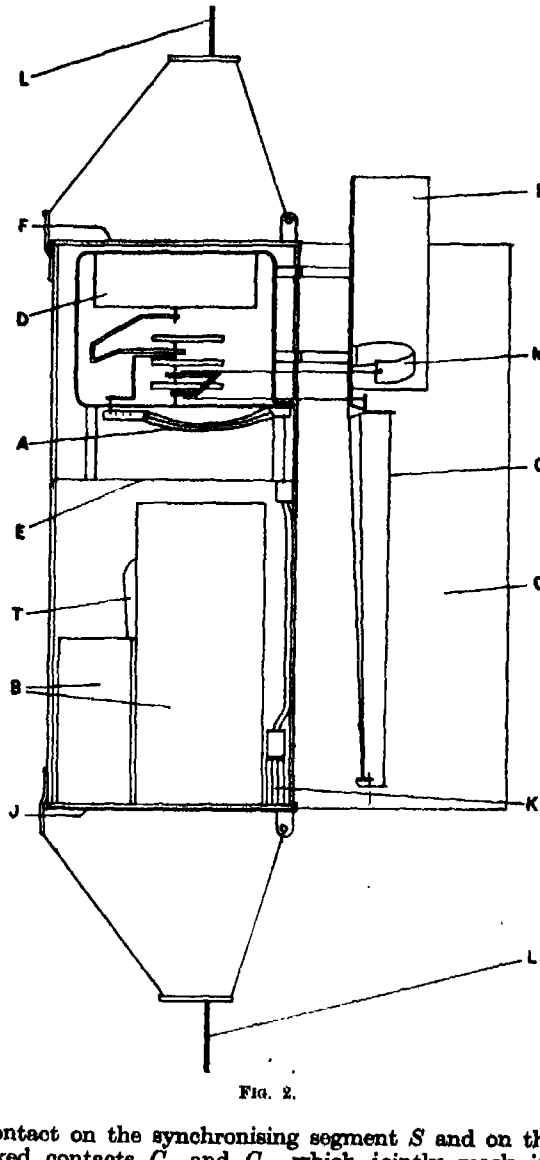

FIG. 2.

contact on the synchronising segment S and on the fixed contacts C_1 and C_2, which jointly mark its revolution into three parts, temperature, barometer and humidity respectively. The relatively long contact at S is for the purpose of emitting a longer signal in order to synchronise the recording cylinder at the receiver in a manner already well known in connexion with picture-receivers. The temporal interval between the end of the synchronising signal and the contact with the 'temperature' arm thus depends on the instantaneous position of the latter;

similarly the interval between the signal from C_1 and that from the 'barometer' arm depends on the positions of this pointer, etc. The contact has necessarily to be extremely light, and takes the practical form of a small elastic silver strip. Apart from mere weight, an additional need for lightness is that the contact should not sensibly disturb the position of the instrument pointers. The contact now in use is stated to be satisfactory in this respect, while it is to be noted that a slight disturbance, resulting in a lengthening of the signal, is immaterial in practice since it is the *first* instant of contact that marks the position of the pointer. The rotating arm A revolves once in 33 seconds.

Moltchanoff's original radio-meteorograph was intended primarily for aural receptions on a radio-receiver of normal pattern. The signal impulses were then arranged so as to permit ready aural identification with human interpretation of their meaning. The newer instrument now described is

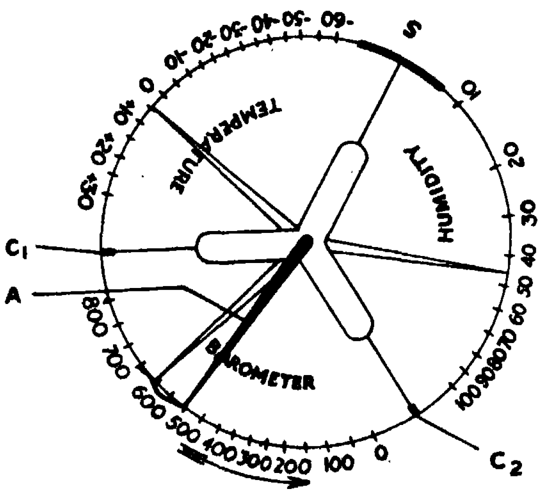

FIG. 3.

particularly designed for automatic recording, giving a record of the three elements which become normal Cartesian graphs by the addition of a scale of co-ordinates. Automatic recording is effected by an ordinary radio receiver followed by a picture-receiver of the rotating cylinder type. A suitable picture-receiver is that due to Prof. Dieckmann. This operates on principles, for example, of synchronising, etc., generally similar to those of the Fultograph receiver already well known in Great Britain, and need not be further described here. The type of record made by the Dieckmann receiver is shown in Fig. 4, which additionally shows the application of a scale of ordinate values covering the ranges measured by the instruments. A graduated graticule is available for application to the record for this purpose, a strip of it being added alongside the record of Fig. 4 to illustrate the assignment of scale values. The scale is applied by reference to the beginning of the signals from the fixed contacts C_1 and C_2.

The meteorological instruments are indicated in Fig. 2. The three measuring elements are the barometric diaphragm A, the bi-metal thermometer M and the hygrometer hairs C. The thermometer and hygrometer are housed in the air channel G, while the former is protected from radiation by the highly polished cylinder H. The clockwork motor which drives the contact-arm is shown at D, holes for winding and control being provided in the cover F. These are all supported on the plate E in the upper part of the casing. The transmitter and its batteries

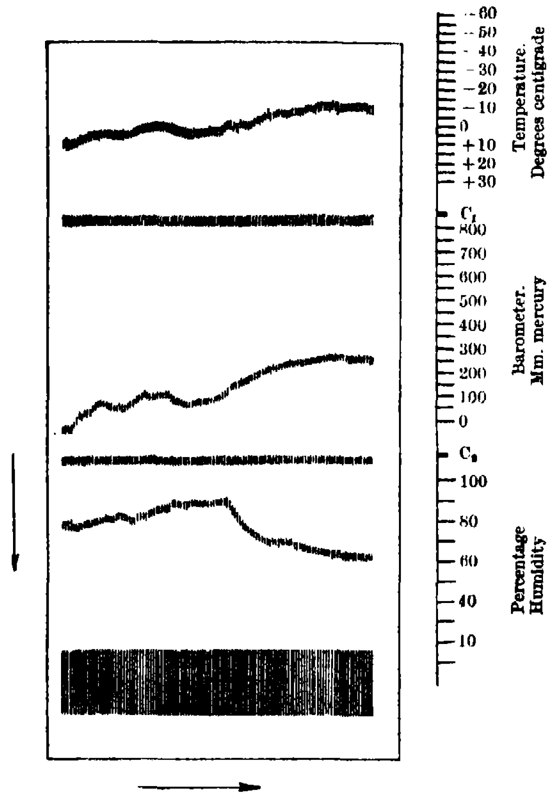

FIG. 4.

sit on an insulating sheet on the bottom-plate and can readily be withdrawn for adjustment or renewal. The plug K completes the circuit to the contact-arm and also to the leads L of the dipole antenna.

The various measuring instruments are calibrated by the makers before delivery. It is stated that the thermometer and barometer need not generally be recalibrated, but errors can readily be corrected should they develop. In the case of the hygrometer it is necessary to renew the hairs from time to time.

The complete instrument, as shown in Fig. 1, weighs only 2 kgm.; and recording ranges up to 100 km. have been achieved.

J. F. H.

International Association for Testing Materials

THE eighth meeting of the Permanent Committee of the International Association for Testing Materials was held on October 3–4 at Florence under the chairmanship of Dr. Walter Rosenhain, president of the Association. The Committee reviewed the financial position of the International Association and decided to issue a letter, through the president, directing the attention of certain countries to their moral obligations to the Association. Some countries, notably Switzerland, have already contributed more

than their quota and it is hoped that the remaining countries will also make an adequate response to the financial appeal which the Committee has been obliged to make.

The completion and issue of the "Book of the Congress of Zurich in 1931" was reported, and the desirability of securing the further sale of this volume was emphasised. It is believed that the nature and value of this publication have not yet become fully known to many of those who might be interested in it, so that a much larger sale should be attained; this is highly desirable if the future work of the International Association is to go forward vigorously.

The main question dealt with by the Permanent Committee at the Florence meeting was the plan of work to be undertaken at, and in preparation for, the congress which is to be held in London in 1935. It was decided in general terms that the work of the congress should again be organised on lines similar to those which had proved particularly successful at Zurich. The work of the congress will therefore be carried out in four sections or groups, namely: A, Metals (president, Prof. C. Benedicks, Sweden); B, Inorganic Materials, including stone, cement, concrete, etc. (president, Prof. E. Suenson, Copenhagen); C, Organic Materials (president, Dr. F. Barta, Prague); and D, Questions of general importance. For Group D the late Dr. Burgess of Washington had been appointed president. His untimely death unfortunately renders it necessary to appoint a new president for this Group, but the appointment has not yet been made as it was thought desirable to await suggestions from various countries. In each of these Groups only a limited number of subjects will be discussed, the whole of one session being devoted, as was done at Zurich, to the discussion of a single question or group of questions. The selection of subjects with which it is proposed to deal has been provisionally made as follows:

Group A: Corrosion, light alloys, welding, progress of metallography, behaviour under machining and abrasion.

Group B: concrete and ferro-concrete, testing methods for ceramic materials, weathering of natural and artificial stone.

Group C: textiles (artificial silks), wood cellulose, india-rubber (cautchouc), preservation of timber.

Group D: progress in testing machines and measuring appliances, materials of construction in the laboratory and in service, methods and concepts of physics and chemistry in their application to problems of testing materials, sound and heat transmission of materials.

While it has been thought desirable to lay down in these general terms the subjects to be discussed at the congress in London, it is realised that in the intervening period developments may occur which may make an alteration of this programme desirable.

In view of the financial stringency which the International Association feels, in common with the industrial and technical world upon which it depends for support, it may not be possible to issue any intermediate publications such as those issued some eighteen months before the congress at Zurich. None the less, the work of the Association will be carried forward actively, mainly through the presidents of the four Groups and also by a number of international committees which have been appointed. The latter will carry on their work almost entirely by correspondence, but meetings in connexion with them will take place at or immediately prior to the congress in London in 1935.

In spite of exceedingly difficult circumstances, it will be seen that the International Association for Testing Materials is carrying on its work in an active and energetic manner, and an appeal is made for support in all countries both from societies, institutions and industrial firms, and also from all those individuals who are in one way or another concerned with the problems of testing.

The secretariat of the International Association is at Zurich (Leonhardstrasse 27) and Prof. M. Roš, head of the Swiss Federal Testing Laboratory, has consented to retain the office of general secretary until the congress in London. The British headquarters of the association are in the hands of Mr. G. C. Lloyd (honorary secretary and treasurer) at the offices of the Iron and Steel Institute, 28 Victoria Street, London, S.W.1.

Air Waves from Experimental Explosions

THAT the audibility of explosions must be due in some wey to conditions in the upper air at considerable heights above the ground has long been recognised. It is therefore appropriate that experimental explosions should be included in the programme of intensive meteorological research during the Polar Year. The first experiments to be organised in accordance with this programme by Prof. H. Hergesell, president of the International Commission for the Investigation of the Upper Air, took place on December 15. These explosions were at Russian Harbour in Novaya Zemlya and at Oldebroek in Holland. At each place there were to be four explosions, at 6.0, 6.6, 7.0 and 7.6 G.M.T. Four Kühl undographs were to be operated in the neighbourhood of the Russian Harbour explosions, three in Novaya Zemlya and one in Franz Josef Land. Several undographs were to be used in Germany and one, at Flushing, in Holland. For co-operation by Great Britain, the sound-ranging apparatus which is in regular use for recording at Birmingham, Bristol, Cardiff and Nottingham the air waves caused by firing at Woolwich, was available, as well as similar apparatus at Foulness near the mouth of the Thames and at Hythe near Folkestone.

According to newspaper reports, the explosions at Oldebroek were not heard over any large area. The air waves were recorded at Potsdam and at Lindenberg. It is surmised that the photographic records from the other stations in Germany would be sent to a central point to be developed, so that some delay in the announcement of results is to be anticipated.

There was no reception of the air waves at Foulness, Hythe or Nottingham. Definite information is not yet available from Birmingham and Bristol. At the Cardiff station, Cefn Mably, Dr. J. Shaxby obtained a series of records showing disturbances, mostly minute, which were at first thought to indicate the reception of waves from the explosions at Oldebroek, but this interpretation is very doubtful.

Of the reports which have reached the Superintendent of Kew Observatory, in response to a

notice issued to the Press by the Air Ministry, one of the most valuable is from Miss Mabel Williams, who noticed at Cambridge that the window of her room vibrated vigorously at 6.21½, at 6.26½ and again at 7.26½. Sir John and Lady Smith, who were listening at Havering-atte-Bower in Essex, report that, between 19 and 22 minutes after 7, hundreds of birds in the trees surrounding their house suddenly made startled cries as if in danger. A considerable number of people in various parts of England have reported that they heard noises, which they attributed to the experimental explosions, but there was no area in which the sounds attracted general attention, and observers who listened with the intention of timing the series were not successful.

It is in accordance with previous experience that the infra-sonic waves, which carry most of the energy of an explosion, can be effective at great distances, at places where no sound can be perceived by ear. In the present case, the infra-sonic waves seem to have passed over Foulness to make the twigs quiver in the trees at Havering-atte-Bower and to shake the window at Cambridge. The distance from Oldebroek to Cambridge is 400 km.

University and Educational Intelligence

LONDON.—The title of reader in petrology in the University of London has been conferred on Dr. Alfred Brammall in respect of the post held by him at the Imperial College—Royal College of Science.

THE problem of the deaf, especially of their education, training and employment, is dealt with exhaustively in a report by Dr. A. Eichholz (London, H.M. Stationery Office, pp. 206, 3*s*.). The report is based on an investigation begun in April 1930, with the object of clearing up the facts upon which various representations have been made from time to time since 1924 (when the National Institute for the Deaf was founded) to Parliament and to the Ministry of Health and the Board of Education. Comprehensive statistics of the incidence of deafness in adult life are lacking, but indications that deafness of a disabling character exists in a marked degree among the general population are afforded by rejections for ear-diseases of applicants for service in the Army (5 per cent) and Royal Air Force (2 per cent). Among children, some gratifying decreases, attributable to arrangements by local education authorities for inspection and treatment, are reported. The statistics of deaf and dumb children also show a gradual decrease, attributable to improvement in the general health supervision of the population, from 4,173 in 1924 to 3,621 in 1930. The report suggests, *inter alia*, that arrangements for the detection of defects of hearing should be improved by the use of acoumetric apparatus such as the audiometer now used in many American cities, that the Ministry of Health and Medical Research Council should institute a study of the age incidence, causes and treatment of ear defect, that provision for vocational courses for deaf people should be made in the north, west and midland districts of England and in South Wales, and that a secondary school for the deaf should be provided.

THE International Federation of University Women (Crosby Hall, Cheyne Walk, S.W.3) has published a full report of its sixth conference, held last August at Edinburgh. Created, mainly on American and British initiative, in the year following the War as a means of promoting international understanding and friendship, this organisation has year by year extended its membership until it now comprises, in addition to those of the United States and the British Empire, associations of university women of every country of Europe (outside Russia), and Egypt, Palestine, Mexico and Brazil. The list of participants in the conference reaches the imposing total of 575 and although the American and British largely predominated, thirty countries in all were represented. Among the subjects dealt with were: international aspects of the development of science, co-ordination of university standards, the contribution of women to the newer knowledge of nutrition, epidemics of plant diseases and, in one of the sectional meetings, the careers open to women biologists. At this sectional meeting there was a consensus of opinion that it is far more difficult for women than for men to obtain work as biologists, that this is not due to their unsuitability for any of the kinds of work available (with the possible exception of certain kinds of tropical field work) and that there is consequently a waste of women biologists. Two members undertook to investigate this matter. Statistics of membership of the affiliated associations show that seventy per cent of the aggregate total are American university women. These constitute the financial backbone of the Federation. The German membership decreased heavily in 1932, while the Austrian increased by *seventy-six per cent*.

EDUCATION in Belgium is described by Dr. J. F. Abel, of the United States Office of Education, in a pamphlet of 145 pages prepared after investigation on the spot last year and now published by the Government Printing Office, Washington. One of the most striking facts to which Dr. Abel directs attention is the very heavy enrolment in the kindergartens —nearly a quarter of a million; this being nearly as large a proportion of the total number of children of kindergarten age as the proportion of the enrolment in primary schools to the number of children of primary school age. The secondary school curricula in Belgium have lately been remodelled so as to lessen school work and give more opportunity for recreation and physical development, the number of school hours being limited to 34 a week and teachers being warned that assigning tasks for home study is generally useless, and that it is habit rather than subject matter that the pupil is to acquire. Physical and biological sciences figure in the curricula of all divisions of secondary schools, but the time allotted is in general only two hours a week. Commenting on the problems arising out of bilingualism, Dr. Abel observes that the Belgians have proved that language unity is not necessary to, or perhaps advantageous for, national unity where appropriate arrangements are made in the schools. In the attempt to give effect to the principle of equal instruction for equal intelligence, very elaborate procedures have been prescribed for the guidance of the committees entrusted with the task of selecting children in primary schools for bursaries; the model school card enumerates forty-one characteristics to be estimated in the case of each pupil. An interesting account is given of the Colonial University, which selects annually twenty young men who contract to serve at least three years in the Congo after a four years' course.

Societies and Academies

LONDON

Physical Society, Dec. 16.—Allan Ferguson and J. T. Miller: A method for the determination of the specific heats of liquids, and a determination of the specific heats of aniline and benzene over the approximate range 20° to 50° C. The specific heats of aniline and benzene are determined by measuring the electrical power E^2/R necessary to hold the temperature of a calorimeter and its contents steady at various temperature-excesses.—**E. V. Appleton and G. Builder**: The ionosphere as a doubly refracting medium. In a previous communication the occurrence of wireless echo doublets was described and was provisionally attributed to the influence of the earth's magnetic field on the dispersive properties of the ionosphere. A more extended study of the subject, which has included an experimental determination of the polarisations of the doublet components, has confirmed this hypothesis. In south-east England, for ionospheric reflection at vertical incidence, the echo component of lesser delay is in general of right-handed, and the component of greater delay of left-handed, circular polarisation, but this temporal sequence should be reversed in the southern hemisphere and in certain special circumstances in the northern hemisphere.—**M. Taylor**: The Appleton-Hartree formula and dispersion curves for the propagation of electromagnetic waves through an ionised medium in the presence of an external magnetic field. (1) Curves for zero absorption. The curves are drawn to show the value of the squares of the indices of refraction and attenuation as functions of the electron density for a series of twelve frequencies, which are chosen to illustrate the various classes of curve and the boundary curves separating the classes and, in the case of frequencies of more than 1·321 megacycles per second, the various regions of short and ultra-short waves. The derivation and general properties of the Appleton-Hartree formula and the various possible modes of propagation are also discussed. The disperson curves are classified according to the infinities they contain and a diagram is given to show how the classes of curve holding for any angle of inclination of the direction of propagation to the magnetic field H depends on the ratio of the longitudinal component of H to H itself.—**L. F. Bates**: A new apparatus for the measurement of the earth's magnetic field. A small cylinder of mumetal is wound with fine wire, the ends of which are connected to wires forming a torsional suspension. This cylinder is placed with its centre at the mid-point of a Helmholtz coil system with its axis adjusted to coincide with the direction of the component of the earth's field which is to be measured, the suspension being perpendicular to the component. The current through the coil system can be adjusted so that there is no deflection of the suspended cylinder when the current in the solenoid wound upon it is reversed, in which case the calculated field produced by the coils is equal to the required component.—**E. G. Richardson and E. Tyler**: The flow of liquid suspensions. Measurements of the velocity from point to point in a liquid rotating in the space between two concentric cylinders, of which the outer rotates while the inner is still, have been made by means of a hot-wire anemometer. In a suspension, the velocity gradients are abnormal but can be explained in terms of a variable viscosity, which is a function of the velocity gradient.—**Lewis Simons and E. H. Smart**: A model to illustrate the motion of a diatomic rotator with two degrees of freedom. An arm 5 in. long is pivoted at one end and carries at the other end a small electric lamp which is thus capable of moving on the surface of a sphere about the pivot as centre. The two angular velocities $\dot{\Phi}$ and $\dot{\theta}$ can be independently controlled by two hand-regulated motors: Φ is the azimuthal and θ the co-latitudinal angular co-ordinate of the arm. If $\dot{\Phi}$ and $\dot{\theta}$ are commensurable, the resulting figure traced out by the lamp remains stationary in space. This path represents the motion of one of the atoms of the rotator, which has two degrees of freedom.

PARIS

Academy of Sciences, Nov. 7.—J. Costantin: The secret of Java. An account of the methods used to combat the sugar cane disease (Sereh) of Java, with special reference to the favourable effects of growing the young shoots at high altitudes.—**Bertrand Gambier**: Ruled algebraic surfaces and their singularities.—**Potron**: Certain conformal transformations in a Riemann space.—**Vignaux**: Riemann's method of summation.—**Nikola Obrechkoff**: The summation of the Fourier trigonometric series and conjugated series.—**P. Papcovitch**: General expressions for the components of stresses, containing as arbitrary functions only harmonic functions.—**J. Haag**: The improvement of the isochronism of pendulums by the use of elastic stops. The method is not new, but has hitherto been based empirically on experiment. A theoretical study is given, defining the characteristics of the best arrangement.—**R. Thiry and L. Sackmann**: A special arrangement of the stream lines in front of an obstacle. Outline of an experimental method with a hydrodynamic tunnel, with some preliminary results.—**P. Idrac**: Ultra-sensitive recorders of variation of altitude and temperature for aeroplanes.—**Kivelivotch**: Some particular cases of the problem of three bodies with impacts.—**Th. V. Ionescu and C. Mihul**: Ionised gases in the magnetic field: pressures below 0·001 mm. mercury. Continuation of experiments on the influence of pressure and of water vapour on the conductivity of ionised gases. Curves are given showing the conductivity as a function of the magnetic field.—**G. Athanasiu**: The sensibility in the spectrum of photo-cells with electrodes of copper covered with cuprous oxide. It is concluded that, in general, a copper electrode covered with a thin layer of cuprous oxide and dipped into neutral or alkaline electrolytes gives a negative E.M.F. on illumination. The effect commences at about 6500 A., increases as the wave-length diminishes, reaches a maximum and diminishes again towards the extreme violet of the visible spectrum. The method of preparing the film affects the results.—**E. Carvallo**: The effect observed by Miller at Mount Wilson was the Esclangon effect. The author gives another interpretation of Miller's experiments. He regards them as confirming and generalising Michelson's law, that the earth's velocity introduces no difference of path between the two rays of the interferometer.—**Yves Rocard**: The theory of critical opalescence.—**S. Y. Sze**: The β-rays emitted by the active deposit of actinium.—**Francis Perrin**: The average life of activated atomic nuclei. Probable cases of the impossibility of the γ-emission.—**G. I. Costeanu**: The measurement of electromotive forces in liquid ammonia. Details of the experimental

method and data for two cases.—**B. Bogitch**: The use of diaphragms in the commercial electrolysis of metals. Advantages are claimed for the use of impermeable diaphragms. High purity of the anodes is less necessary; the cathodes can be as pure as desired and the volume of electrolyte in circulation is considerably reduced. There is one disadvantage: there is an increase in the electrical energy used—about twenty per cent in the apparatus described.—**Mlle. Suzanne Veil**: Rhythmic phenomena observed in the electrolytic precipitation of colouring matters.—**Mme. Ramart-Lucas** and **M. Trivédi**. Colour and chemical behaviour in the cinnamic series.—**E. Darmois** and **R. Chalin**: The cryometry of some electrolytes in the fused hydrate $CaCl_2, 6H_2O$.—**E. Vellinger**: The superficial properties of india-rubber.—**A. Demolon** and **E. Bastisse**: The influence of the anions on the flocculation of colloidal clay by potassium salts.—**André Chrétien** and **Pierre Laurent**: A method of physicochemical analysis in organic solution by measuring the specific inductive power. Variations of the dielectric capacity can serve to detect acid and basic characters in the absence of water. Thus in benzene solution, mixtures of quinoline and phenol give indications of the formation of a combination of equal molecules.—**Pierre Jolibois** and **Louis Cloutier**: The basic salts of lead.—**Firmin Govaert**: The determination of the halogens in organic substances by the sodammonium method.—**P. Carré** and **D. Libermann**: The chlorides of the arylsulphurous acids and mixed aryl and alkyl sulphites. Thionyl chloride and aryl sulphite react according to the equation $SO(OAr)_2 + SOCl_2 = 2ArO.SOCl$. The chloride thus formed cannot be distilled without decomposition, but its existence is proved by its reactions, notably with formic acid and with alcohols. Mixed aryl alkyl sulphites are formed in the latter reaction.—**Georges Lévy**: Some derivatives of β-ethylnaphthalene.—**Pierre Bedos** and **Adrien Ruyer**: Some reactions of cyclohexadiene.—**A. Demay**: The existence of an antestephanian arc and on the continuity of the apparent thrusts towards the exterior of the arc from the Lyonnais to Corrèze.—**Jean Goguel**: The tectonic of the Luberon (Provence).—**Jacques Fromaget**: The structure of the indosinides.—**A. Rivière**: Contribution to the study of the Palæozoic of the central Elbourz.—**Jean Legrand**: The utilisation of observations of height indicators on rivers for the purpose of research on climatic cycles.—**J. Lacoste**: An earthquake with Mediterranean epicentre.—**Jean Lugeon**: The solar eclipse of August 31, 1932, and investigation by atmospherics.—**St. Jonesco**: The movements of the flowers of *Ipomœa purpurea*. The flowers of this species are continually in motion from the bud stage to the formation of the fruit.—**P. Martens**: Alternation of phases and sexuality in a conidian cycle in *Pholiota aurivella*.—**F. Obaton**: The presence of saccharose in the branches and leaves of *Euonymus europœus*.—**Jean Chaze**: The existence of a new active principle in *Bryonia dioica*.—**Raoul Lecoq**: The B vitamins and the utilisation of the lipides. The assimilation of lipides by the organism, like proteins and glucides, requires the presence in the ration of sufficient quantities of B vitamins.—**J. Giaja** and **Ilija Dimitrijević**: The influence of the surrounding temperature on the effect of pyretic substances.—**Marcel Florkin**: The dissociation curve of oxyhæmerythrin in the cœlomic liquid of *Sipunculus*.—**Charles Dubois**: The specificity of the allergic reaction as a method of diagnosis of ovine melitococcia.

Geneva

Society of Physics and Natural History, Nov. 17.—**E. Friedheim**: Two accessory respiratory ferments of animal origin. The tegumentary pigments of *Halla parthenopea* and of the sea urchin, *Sphœrechinus granularis*, possess the function of very considerably increasing the respiration of non-impregnated eggs of sea urchins and of non-nucleated red blood corpuscles. It is a case of catalysis due to the reversibility of the oxidation and reduction of the pigments. The Halla pigment can be titrated electrometrically.—**P. Rossier**: (1) Spectrophotographic photometry. The author gives a second approximation of the coefficients of experimental formulæ established before.—(2) The rôle of atmospheric humidity in astronomical photography. Certain coefficients of the formulæ studied in the preceding paper vary with the vapour pressure of atmospheric moisture.—(3) The refraction correction to be applied to differential astronomical observations. Micrometric observations of precision are vitiated by atmospheric refraction if the two stars observed are of different colours. The constants of spectral sensibility of the eyes now appear to be sufficiently well known to render it possible to calculate the effect. These systematic errors may be too large to be neglected.—**J. Weigle**: The orientation of non-polar molecules by a dipole. The author shows that a molecule with a permanent electric moment placed in a medium the molecules of which are non-polar but anisotropic, produces an orientation of these molecules. This orientation of the neighbouring medium should affect either the measurement of the permanent electric moment or the refractive index of the medium. By measuring the latter the author shows that interesting information on the form and structure of the molecules can be obtained.—**Ch. H. Wakker** and **B. Susz**: A rapid method of quantitative spectroscopic analysis. The method consists in carrying out a photometric measurement of a selected line of the spectrum emitted by the element to be determined. The measurement is made by direct observation with the spectroscope without making use of photography.—**E. Briner** and **H. Biedermann**: Ozone the only persistent allotropic form of oxygen produced in appreciable quantity by the silent electric discharge. The products resulting from the action of the silent discharge on oxygen, working with different forms of apparatus both at low and high frequency, were submitted to fractional distillation. No allotropic modification of oxygen other than ordinary ozone could be found.—**R. Wavre**: The polydromes of potentials.—**H. Lagotala** and **Ch. Couchet**: Note concerning the tectonic of the cupriferous region of the middle Congo. The authors have proved the mylonitised zones in the grits, limestones and at the contact of the grits and limestones. They have remarked the frequency of the sub-horizontal movements and the presence of laminations some of which are mineralised. In certain cases a single layer is separated for a considerable distance. The age of these separations appears to be earlier than the formation of the faults.—**G. Tiercy**: The hypothesis of continental drift: the chronological succession of the first upholders. The order given is as follows: 1668, Le R. P. Francois Placet: 1858, Antoine Snider Pelegrini: 1889, R. Mantovani: 1890, J. A. Boulanger.

Washington, D.C.

National Academy of Sciences (*Proc.*, 18, 609–632, Oct. 15, 1932).—**Thomas Wayland Vaughan**: The fora-

minifera genus *Orbitolina* in Guatemala and Venezuela.—**Thomas Wayland Vaughan** and **W. Storrs Cole**: Cretaceous orbitoidal Foraminifera from the Gulf States and Central America. A new type of orbitoid from the Upper Cretaceous of the Gulf coastal plain and another specimen, both from oil well cores, are described and illustrated.—**Robert Balk**: Structure and correlation of metamorphic rocks in south-eastern New York. The older view, due to Dana and Merrill, following Mather, regarded the metamorphic sediments of this area as equivalents of the fossiliferous Cambro-Ordovician sequence north-west of the Hudson Highlands. Later, Berkey tentatively regarded the highly metamorphic series as Pre-Cambrian. Detailed field work over the area, of which a long abstract with map and diagrams is given, supports the older view.—**Sterling Emerson**: Chromosomes rings in *Œnothera*, *Drosophila* and maize. It is suggested that the postulates of 'inverted section' and 'differential segments' are not in accord with published data and are unnecessary to account for the small amount of crossing-over observed.

Forthcoming Events

CONFERENCE OF EDUCATIONAL ASSOCIATIONS, Jan. 2–9. At University College, Gower Street, W.C.1.
The Right Hon. the Earl of Athlone: Presidential Address on Jan. 4, at 3.
Joint Conference on "The Trend of Education". Speakers: H. Ramsbotham, Miss W. Mercier and J. E. Barton, on Jan. 2, at 5.

PHYSICAL SOCIETY, Jan. 3–5. Twenty-third annual exhibition of scientific instruments and apparatus at the Imperial College of Science and Technology, South Kensington, S.W.7, at 3–6 and 6–10.
Dr. Allan Ferguson: "Surface Tension and its Measurement", on Jan. 3, at 8.
R. A. Watson Watt: "Cathode Ray Oscillography", on Jan. 4, at 8.
F. Hope-Jones: "Time Measurement: Old and New", on Jan. 5, at 8.

SCIENCE MASTERS' ASSOCIATION, Jan. 3–6. Annual Meeting at the University of Bristol.
Prof. A. M. Tyndall (Presidential Address): "Gaseous Ions".

GEOGRAPHICAL ASSOCIATION, Jan. 4–6. Annual Conference at the London School of Economics and the Imperial Institute.
Dr. H. R. Mill (Presidential Address): "An Approach to Geography", on Jan. 4.

MATHEMATICAL ASSOCIATION, Jan. 5–6. Annual Meeting at the Institute of Education, Southampton Row, London, W.C.1.
Prof. G. N. Watson (Presidential Address): "The Marquis and the Land Agent: a Tale of the Eighteenth Century", on Jan. 5, at 3.45.
Discussion on "The Study of Statistics in a School Course", to be opened by F. Sandon, on Jan. 6, at 2.15.

Official Publications Received

GREAT BRITAIN AND IRELAND

Proceedings of the Royal Society. Series A, Vol. 138, No. A836, December 1. Pp. 479–722. (London: Harrison and Sons, Ltd.) 12*s*.

Proceedings of the Royal Irish Academy. Vol. 41, Section B, No. 6: Observations on the Cytology of *Opalina ranarum* and *Nyctotherus cordiformis*. By Ruth Patten. Pp. 73–94 + plates 6–7. (Dublin: Hodges, Figgis and Co.; London: Williams and Norgate, Ltd.) 1*s*.

The Journal of the Ipswich and District Natural History Society. Edited by Henry Ogle. Vol. 1, Part 3, November. Pp. 141–196. (Ipswich.)

Proceedings of the Linnean Society of London. Session 1931–32, Part 6. Pp. 167–220. (London: Linnean Society.) 2*s*.
